Details of expenditure on basic research in the United States are given in various surveys published by the National Science Foundation, but the report "Basic Research—A National Resource", recently issued by the Foundation, is more in the lineage of Vannevar Bush's "Science—The Endless Frontier" and the Steelman report, "Science and Public Policy". It attempts to convey to the general citizen the meaning of basic scientific research and its bearing on the national economy, welfare and security. The growth of basic research in the United States is briefly described in a chapter which illustrates some of the possibilities implicit to-day in virus research, in translation by electronic methods and in the study of other problems of social communication in leadership. After a brief reference to some unsolved problems, the following chapter outlines the present position of basic research in the United States, both in scale and in organization, while in the final chapter the strengthening of basic research is discussed and various suggestions listed in the general summary are amplified.

Stress is laid upon the establishment of more favourable conditions for its continued growth, including an increasing awareness on the part of the public of the methods, aims and significance—cultural as well as material—of basic research, as well as upon increased financial support. A more active participation by private industry is particularly urged as well as reduction in the amount of development work in universities and colleges under contract with Government agencies. Although in general terms the report contains little that is not to be found in the Barlow and other reports in Great Britain, it presents the case for basic research in cogent terms that are equally applicable in Britain and elsewhere.

ORIGIN OF CHONDRULES IN METEORITIC STONES

By DR. L. J. SPENCER, C.B.E., F.R.S.

THE chondrules (χόνδρος, a grain) in meteoritic stones are quite distinct from the spherulites in terrestrial volcanic rocks and from the ooliths and sand grains in sedimentary rocks. They occur in chondrites (chondritic meteoritic stones); other rarer meteoritic stones in which they are not present are classed as achondrites. They are usually quite small (1–3 mm.), about the size of millet seed, usually spherical, and are embedded in a finely brecciated matrix of the same materials (olivine, pyroxene, felspar, glass, nickel-iron, etc.) of which they themselves are composed.

Their mode of origin has long been a puzzle, giving rise to much speculation. In recent reviews[1] of the various hypotheses, mention has been made, but with little support, of an early suggestion by H. C. Sorby[2] of glassy globules of 'fiery rain'. This mention of 'fiery rain' calls to mind the findings at the meteorite craters of Wabar in Arabia[3].

Mr. H. St.J. B. Philby's expedition in 1932, with eighteen Arabs and thirty-two camels wandering in the desert for three months, had the object of finding the legendary city of Wabar, supposed to have been "destroyed by fire from heaven". Two meteorite craters were found, and there were indications of others buried beneath the desert sand; their walls are formed of cindery blocks and bombs of silica glass. Nearby, pieces of meteoritic iron were collected, the largest weighing 25 lb.; but a mass of iron as "big as a camel" could not be found. The locality is known to the Arabs as Al Hadida (place of the iron). Scattered around were numerous shining black pellets. These were thought by the Arabs to be pearls, blackened by the fire, that had been worn by the ladies of the court of the wicked king 'Ad ibn Kin'ad. With a lust for wealth, the Arabs filled the camel saddle-bags with these 'pearls', but on the return to Mecca they were rejected by the dealers and thrown away. Fortunately, a few were preserved in Mr. Philby's collection. These consist of a vesicular white silica-glass (SiO_2, 92·88 per cent), coated outside with a lustrous black glass (SiO_2, 87·45 per cent), with some iron and nickel.

Larger blocks or bombs show in some cases a corrugated surface resembling ropy lava, and covered with minute pimples, which perhaps represent dew-drops of silica. Broken surfaces show a breccia of white, grey, and black glass with a few shattered grains of quartz, and many round bubbles varying widely in size. Thin sections under the microscope show in addition large numbers of minute black specks. These specks I had at first assumed to be small holes filled with the grinding and polishing materials used in the preparation of the sections. But Dr. Leonard Hawkes, when he crushed a fragment of the glass on a microscope slide, saw minute metallic spheres rolling about. A piece of the glass crushed (not ground) in an agate mortar yielded a powder from which a magnetic needle picked up bunches of bright spheres by the thousands. These range from 0·1 to 0·0005 mm. in diameter. Two counts of the black dots over areas of a square millimetre on the thin sections gave estimates of one and two million in a cubic centimetre of the glass.

In a solution of copper sulphate the spheres become coated with copper. Analyses gave: Fe 91·2, Ni 8·8 per cent; Fe : Ni = 10·4, as compared with 12·6 in the meteorite. X-ray examination by Dr. F. A. Bannister showed the material to be body-centred cubic α-iron. Metallographic examination by Dr. J. M. Robertson showed that the smaller spheres consist of a single crystal, while larger ones consist of several crystals with inclusions (probably silica-glass) between the irregular boundaries of the grains.

At Wabar there evidently was a shower of large masses of meteoritic iron. The sudden transformation of the kinetic energy into heat gave rise to violent explosions, and broken fragments of iron were ejected from the craters. The Earth's atmosphere was blasted aside by vapours of iron and nickel, and of silica (from the desert sand). Temperatures were far in excess of:

	Nickel (° C.)	Iron (° C.)	Silica (° C.)
Melting point	1,452	1,535	2,900
Boiling point	2,900	3,200	3,500?

A rain, or rather drizzle, of globules of molten nickel-iron and silica fell into pools of boiling silica. Conditions such as these, with some variations, would seem to be quite suitable for the formation of chondrites.

A shower of hail-stones into a mush of broken snowflakes (both grown from water-vapour) would produce a somewhat similar structure. Curious hail-stones fell at Menabilly in Cornwall on October 20, 1791. One of them, weighing nearly one ounce, was sketched by Philip Rashleigh and a glass model was made. Enclosed in clear ice were four white spherical hail-stones of the usual kind[4]. This is perhaps another example of chondritic structure.

At other meteorite craters different conditions have prevailed. The Tunguska meteorite of 1908 in central Siberia appears to have been entirely vaporized, and only quite recently have traces of meteoritic material been detected in soil samples[5]. The Meteor Crater in

Arizona shows silica-glass, and from the soil of the surrounding country globules of nickel-iron have been collected with a magnetic rake. Magnetic globules have also been collected from the soil at the place of fall in 1947 of a large shower of iron meteorites in the Sikhote-Alin Mountains in eastern Siberia; but here they represent drops of molten material swept from the surface during passage through the Earth's atmosphere. When steel plates are cut with the oxy-acetylene blowpipe, showers of sparks fall to the ground as minute globules of magnetite, and quantities can be separated from floor sweepings.

The bright streaks radiating from some of the larger craters on the Moon probably consist of myriads of tiny spheres of nickel-iron from the vaporization of iron meteorites[6].

According to Bode's law (1772) on the relative distances of the planets from the Sun, there is one missing between Mars and Jupiter. How this catastrophe happened will never be known. However, it seems safe to assume that the asteroids between Mars and Jupiter are fragments of the missing planet. The largest, Ceres, 480 miles in diameter, was the first to be discovered in 1801; other large ones are Pallas (306 miles), Vesta (241), and Juno (121); others, amounting to more than 1,500, are much smaller, and no doubt fragments are plentiful. All these exert mutual attractions, and their orbits have a high degree of eccentricity, overlapping one another and even the orbit of the Earth. From the trajectory of the Sikhote-Alin meteorite of 1947, its orbit has been calculated to embrace the zone of asteroids[7]. Under such conditions, there are good chances for frequent and violent collisions, resulting in further breaking up, brecciation, melting, vaporization, and rearrangement of materials—just as happened, on a much smaller scale, at Wabar.

Sorby (*loc. cit.*) pointed out that when a fused globule (for example, a blowpipe bead) cools, crystallization starts from the exterior. This is how chondrules have crystallized, and is in complete contrast with the growth of spherulites, where crystallization has proceeded radially outwards from a central nucleus; and of ooliths and pisolites with a concentric structure.

The striking pictures of radiating eccentric chondrules are fully displayed only when the section plane passes through the centre of the sphere and the point where crystallization commenced on the rim. Other section planes perpendicular to this direction may display a barred structure, and sections in other directions will show different patterns.

A THEORY OF ANTIBODY FORMATION INVOLVING EOSINOPHILS AND RETICULOENDOTHELIAL CELLS

By Dr. ROBERT S. SPEIRS

Department of Anatomy, State University of New York, College of Medicine, Brooklyn

THERE have been many attempts to determine the precise cellular mechanisms involved in antibody formation. Although there is general agreement that cells common to the reticulo-endothelial, lymphoid and hæmatopoietic systems are involved, there has been a wide diversity of opinion as to the specific cell or cells in these systems capable of synthesizing the antibody. Plasma cells, lymphocytes, macrophages and certain transitional cells have been proposed as cells capable of producing antibody (see reviews by Taliaferro[1] and McMaster[2]).

The problem of determining the mechanism of antibody production has been complicated by the fact that the site of production varies, depending upon the manner in which the antigen was introduced into the host. Under various experimental conditions, local formation of antibody has been reported in the spleen, regional lymph nodes, bone marrow, thymus, omentum, skin, muscle, fat, etc. Once antibody synthesis has occurred *in vivo*, it is possible to continue the production after transferring viable lymphoid or exudative cells to other animals[3-7] or by culturing the cells *in vitro*[8-12]. However, initiation of antibody synthesis following the addition of antigen to cells *in vitro* has been very difficult or impossible to attain, suggesting that a primary *in vivo* step must be necessary. These and other experiments warrant the proposal that at least two steps are involved in antibody production[13-16]: (1) A primary step which consists of the reaction of certain cells with antigen, bringing about specific enzymatic changes or the formation of an enzymatic template. This step appears to be radio-sensitive and occurs *in vivo* at the site of penetration of antigen into the organism. (2) The second stage consists of the utilization of the specific enzymes for the synthesis of antibody. This step can occur *in vitro* as well as *in vivo*, and appears to be somewhat radio-resistant. It occurs in the lymphoid or reticulo-endothelial tissues of the animal. It is quite possible that these two steps occur in two different cells. However, none of the present theories of antibody production gives a satisfactory explanation for the specificity, mobility and radio-sensitivity of the first step. There appears to be a missing link in the theories, and it is quite possible that some cell, heretofore not considered by immunologists, is involved.

Recent studies in our laboratory[17-20] have indicated that there are three phases of local cellular response at the site of injection of a non-toxic antigen. The first phase, which lasts up to 48 hr., is characterized primarily by a neutrophilia and sometimes a tran-

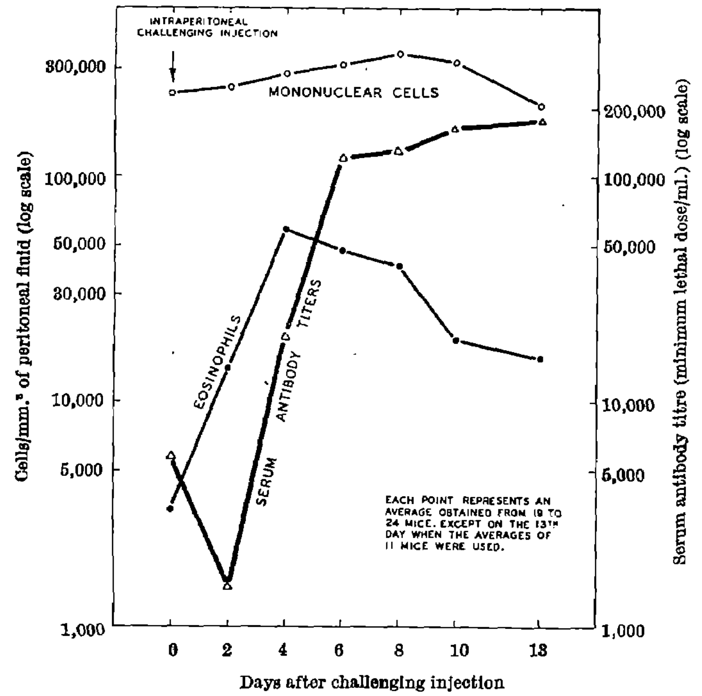

Fig. 1. Local cellular responses and serum antibody titres following a challenging injection of tetanus toxoid in immunized mice (semi-log plot)

sitory eosinophilia. The second phase is characterized by a relatively large prolonged accumulation of eosinophils, reaching a peak on the fourth day after antigen injection. This phase occurs only in animals capable of rapid formation of large amounts of antibody and does not occur in passively immunized animals[21,22]. The third phase is characterized by an increase in local histiocytes (mononuclear cells) and a stimulation of the draining lymph nodes. The time relationship of the second and third phases with the appearance of serum antibody is shown in Fig. 1.

It may be seen that the accumulation of eosinophils precedes the appearance of serum antibody, otherwise the logarithmic increase in these cells is very similar to the logarithmic rise in antibody titres. Moreover, there appears to be a close correlation between the number of eosinophils responding to an injection of antigen, and the resulting serum antibody titres. Factors, such as large doses of cortisone or whole-body X-irradiation which inhibit antibody formation, also inhibit the accumulation of eosinophils[23,24]. Furthermore, in irradiated animals which were allowed to recover before challenging, a prolonged local eosinophilia was observed that coincided with a prolongation of the time for peak serum antibody titres. Irradiation appears to decrease the number of reticulo-endothelial cells capable of phagocytizing the eosinophils and accounted for the slow rate of removal of these cells (unpublished results). Additional experiments have indicated that eosinophils do not contain measurable amounts of antibody, but as they are phagocytized after coming into contact with the antigen, there is a concomitant appearance of antibody in the blood serum.

The preceding findings and other experiments have led us to believe that eosinophils are involved in the initiation of antibody synthesis[25,26]. I suggest the following working hypothesis: Antigen introduced into an organism produces two general types of cellular reactions. First there is a migration of granulocytic cells into the inflamed area. If the host has been previously exposed to the antigen, there is a specific eosinophil response at the site of injection and in the region of antigen fixation. The eosinophils are chemotactically attracted to the antigen and react with it, producing specific enzymatic changes on or within the cell. The second step involves the phagocytosis of eosinophils by reticulo-endothelial cells and the utilization of the specific enzyme by these cells to form antibody. During and following the process of antibody formation, reticulo-endothelial cells undergo nuclear changes, increase their cytoplasmic basophilia (pyroninophilia) and are known as plasma cells[8,12].

The chief merit of the above hypothesis is that it directs attention to the fact that granulocytic cells, such as the eosinophil, may take an important role in antibody formation. It would explain the repeated observations of the close association of eosinophils and plasma cells, and the role of these cells in immune reactions. Furthermore, the hypothesis would explain why reticulo-endothelial cells are capable of continuing antibody production *in vitro*, but are incapable of initiating it. The ability of an animal to form antibody depends upon two factors: the number of eosinophils responding to the antigen, and the capability of phagocytic cells to remove the eosinophils after they have been in contact with the antigen. It is possible that some of the diseases of hypersensitivity may be due to a failure of phagocytosis of eosinophil cells and utilization of the enzymatic templates by reticulo-endothelial cells to form antibody. Further experiments are in progress to elucidate the role of these cells in defence mechanisms.

POSSIBLE POLYMORPHISM OF BOVINE α-LACTALBUMIN

By B. S. BLUMBERG* and M. P. TOMBS
Department of Biochemistry, Oxford

OPPORTUNITY arose during recent trips to Iceland and Nigeria to collect samples of milk from the indigenous herds of cattle. These were examined to determine the type or types of β-lactoglobulin they contained.

There are two β-lactoglobulins[1], namely, β_A and β_B, distinguishable by paper electrophoresis. Aschaffenburg and Drewry[2] have studied their incidence in British breeds, and by family studies have demonstrated their genetic determination. Their presence or absence is determined by two allelic autosomal genes, and all three phenotypes, β_A, β_B and β_{AB}, have been identified.

Samples of milk were prepared for paper electrophoresis according to the method of Aschaffenburg and Drewry[2], and run on Whatman *3MM* paper for 17 hr. at 2 m.amp./cm. width of paper and a potential drop of about 1·5 V./cm. length of paper, in veronal buffer $I = 0{\cdot}05$, *p*H 8·6 in a 'Durrum'-type apparatus[3]. Staining was with alcoholic bromphenol blue, and washing with 2 per cent acetic acid and tap-water.

The Nigerian cattle were White Fulani or Lyre-horned Zebu[4] from the stock farm of the Veterinary Research Station, Vom. They are big humped animals, with large dewlaps and frequently extremely large horns. They are similar in appearance to the Brahmin cattle of the East. They are thought to have been brought into Nigeria by the nomadic Fulani people. Twelve of the specimens were from White Fulani–Friesian crosses.

Samples from Icelandic cattle were collected from various dairy herds on the island. The Icelandic breed is thought to have originated in Norway, and to have been isolated for a considerable period. The Icelandic cattle were selected so as to be free from close interrelationships. Some sister and mother–daughter pairs were present in the Nigerian cows.

The distribution of the β-lactoglobulin phenotypes is shown in Table 1. They fit the predictions of the Hardy–Weinberg law quite well. In the Nigerian sample the Friesian–Fulani crosses are included. Their omission does not significantly alter the results.

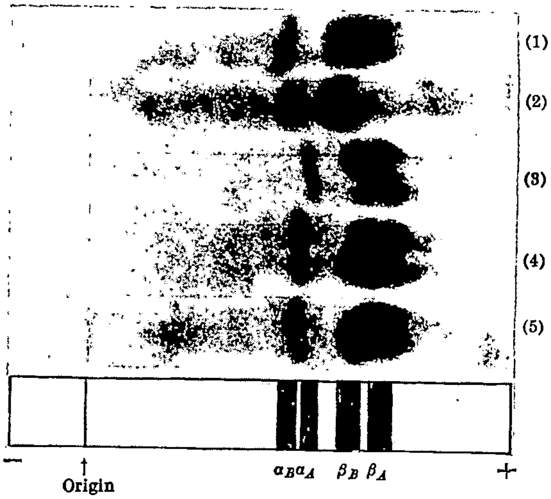

Fig. 1. Examples of electrophoresis strips: (1) Icelandic, α_B, β_{AB}; (2) Fulani, α_{AB}, β_B; (3) Fulani, α_A, β_{AB}; (4) Fulani, α_B, β_{AB}; (5) British, α_B, β_{AB}

There was no significant difference between the incidences in the Zebu, Icelandic or British breeds. (For Zebu $P > 0{\cdot}2$, for Icelandic $P > 0{\cdot}3$, each compared to British incidences taken from Aschaffenburg and Drewry[2].)

During electrophoresis of the Fulani samples a doubling of the α-lactalbumin band was noticed in some cases. Where the two bands were seen, one of them appeared to correspond in mobility with the α-lactalbumin previously found in British breeds, while the other moved more rapidly. Further search revealed a sample containing only the fast-moving

Table 1. INCIDENCE OF β-LACTOGLOBULINS AND α-LACTALBUMINS IN NIGERIAN (WHITE FULANI) AND ICELANDIC COWS
The predicted incidence is determined from the Hardy–Weinberg law. The incidence in combined British breeds is taken from Aschaffenburg and Drewry. *P* is determined by the χ^2 test

Phenotype	Nigeria (W. Fulani)				Iceland				British breeds	
	Observed No.	Observed incidence	Predicted No.	Predicted incidence	Observed No.	Observed incidence	Predicted No.	Predicted incidence	Observed No.	Observed incidence
β_A	3	0·052	2·4	0·041	6	0·115	5·8	0·112	21	0·075

β_A	0	0	2	2
β_{AB}	1	0	12	13
β_B	0	12	19	31
Total	1	12	33	46

---

* Fellow of the Arthritis and Rheumatism Foundation.

α-lactalbumin. No fast α-lactalbumins were found in the Fulani–Friesian crosses. The incidence of each of the phenotypes in the pure Fulani animals only is shown in Table 1.

The distribution of the three types agrees closely with the predictions of the Hardy–Weinberg law. Although too few samples have been examined to provide family studies, by analogy with the case for the β-lactoglobulins, it is suggested that these α-lactalbumins are also genetically determined. The symbols α_A, α_B are given to the proteins, and the symbols $L^A{}_a$, $L^B{}_a$ assigned to the genes presumably determining their presence. α_A is the faster moving component and α_B the slower on paper electrophoresis under the conditions stated above.

All twelve paired α-lactalbumins were found in animals which produced only β_B-lactoglobulin. This association is significant at less than the 5 per cent level. The one sample with only α_A-lactalbumin was found in a β_{BA}-producer (Table 2).

This might be genetic association through close linkage with selection or due to some physiological effect in the mammary gland. The fast-moving α_A-lactalbumin has not so far been found in any British breed, nor in the Icelandic. This protein may therefore provide a marker by which the affinities of the Zebu cattle, and indirectly the Fulani people associated with them, may be traced. The β-lactoglobulins do not appear to be suitable for distinguishing the breeds so far examined. No selective value has yet been found for either the α-lactalbumins or the β-lactoglobulins.

This investigation was supported in part by a research grant, *H*-3161, from the National Heart Institute, U.S. Public Health Service, and the Wenner-Gren Foundation for Anthropological Research. Milk samples were collected from the Nigerian cattle with the permission and help of Dr. J. Taylor, director of the Veterinary Research Station, Vom. One of us (M. P. T.) is indebted to the Agricultural Research Council for a travel grant, and to the Icelandic authorities and Mr. B. S. Benedikz for their assistance in Iceland. Investigations in Nigeria were carried out under the auspices of Prof. B. G. T. Elmes, Department of Pathology, University College, Ibadan.

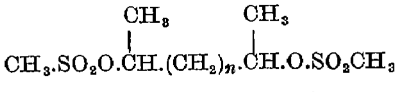
PROTECTION OF AUGUST RATS AGAINST LETHAL DOSES OF A DIMETHYL HOMOLOGUE OF MYLERAN BY ISOLOGOUS BONE MARROW

By PROF. TIMOTHY R. TALBOT* AND DR. L. A. ELSON

The Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, S.W.3

MYLERAN (1 : 4-dimethanesulphonoxybutane), introduced by Haddow and Timmis[1] and clinically by Galton[2], is now well established as a useful agent for the therapy of human chronic granulocytic leukæmia[3]. The hæmatological effects in rats of compounds of the general type $\mathrm{CH_3SO_2.O.(CH_2)_{\mathit{n}}.O.SO_2CH_3}$, of which myleran is the member where $n = 4$, have been studied by Elson[4,5]. These studies have recently been extended to the series:



$$\mathrm{CH_3.SO_2O.\overset{\overset{CH_3}{|}}{C}H.(CH_2)_{\mathit{n}}.\overset{\overset{CH_3}{|}}{C}H.O.SO_2CH_3}$$

made by Timmis and Hudson[6], and the member in which $n = 2$, namely, 2 : 5-dimethanesulphonoxyhexane (*CB* 2348), a dimethyl homologue of myleran, has been found to be three times more active than myleran in depressing the number of neutrophils in the circulating blood of rats[5]. *CB* 2348 is more soluble in water and in organic solvents than myleran, and has a higher rate of chemical reactivity as assessed by the rate of hydrolysis[6].

Clinical trials in malignant diseases indicate that *CB* 2348 has a therapeutic action similar to that of myleran in chronic granulocytic leukæmia[7], and preliminary results by Bierman[8] indicate that it may not be entirely devoid of action in acute leukæmia. In conformity with their effectiveness in granulocytic leukæmia, myleran and *CB* 2348 show a preferential action on the myeloid series of blood cells, and at suitable doses can produce in rats a marked fall in peripheral neutrophils with relatively little effect on lymphocytes or lymphatic tissue. In comparative studies of the effects of cytostatic agents and radiation, Elson[4] has suggested that the myeloid effects of X-radiation can be imitated very closely by compounds of the myleran type, whereas the lymphoid effects of radiation are imitated by compounds of the nitrogen mustard series.

The present interest in protection against lethal doses of X-radiation by means of bone marrow administered shortly after the irradiation suggested that it would be useful to investigate the effectiveness of bone marrow protection against cytostatic agents of the myleran and nitrogen mustard type. Of particular interest is the fact that with myleran compounds the protection against myeloid effects can be studied without the complication of the marked lymphoid effects which are inseparable from myeloid effects in animals treated with X-radiation.

Because of its high biological activity and rapidity of chemical action, making it unlikely that it would persist in the body in an active state for a long period after administration, *CB* 2348 was felt to be particularly suitable for this investigation.

It is now well established that mice exposed to a supralethal dose of X-radiation recover from the radiation injury if they are given intravenous or intraperitoneal injection of isologous, homologous or heterologous bone marrow[9,10]. Rats which have received supralethal doses of X-radiation usually die within 5–6 days, primarily from damage to the small intestine and before hæmatological damage is fully developed. Mice do not die until several days later than this, and death is associated with severe thrombocytopenia, leukopenia and anæmia. Therefore it is not possible to give supralethal doses of X-radiation to rats (in contrast to mice) and then prevent death by bone marrow injection, since gastro-intestinal injury, rather than hæmatopoietic depression, is the major cause of death[11].

---

* Assistant professor of medicine, University of Pennsylvania. This work was conducted during tenure of a Research Fellowship of the National Cancer Institute of the National Institutes of Health.

Rats which have received X-radiation in the lethal, but not supralethal, range can be protected by isologous bone marrow, but not by homologous or heterologous marrow. This is thought to be due to the fact that in order to inhibit the immune response of the recipient animal, thereby permitting the growth of the injected 'foreign' cells, supralethal doses of X-radiation are necessary. Maisin[12] has, however, shown that the 'intestinal' effects of supralethal doses of X-radiation can be reduced by the prior administration of mercaptoethylamine, and about half the rats so treated can be saved by means of an intraperitoneal injection of isologous bone marrow.

Sartorelli and LePage[13] have demonstrated that tumour-bearing mice can be protected against lethal doses of thioguanine by means of injections of isologous bone marrow. Weston[14] has reported bone marrow protection of rats treated with lethal doses of myleran.

Our experiments were carried out in pure line August rats weighing about 120 gm. *CB* 2348, 7·5 mgm./kgm. was administered in arachis oil by intraperitoneal injection. The usual concentration was 0·75 mgm./ml. of oil.

Suspensions of bone marrow were prepared by blowing out the marrow from both femurs of each donor rat into 1 ml. of saline solution. The total final volume of bone marrow suspension, containing the marrow from 4–10 donors, varied from 1 to 2·5 ml. for each group of five recipients. Intravenous injections usually consisted of 0·2 ml. per recipient and intraperitoneal injections 0·5 ml. per recipient. Counts showed that each femur contributed about 35×10^6 nucleated cells. The lateral tail vein was used for the intravenous injections. The bone marrow was injected at various times, from 1½ hr. in one experiment to as long as 4 days in another experiment, after the chemical had been given. In some experiments, Wistar or Marshall rats were used as homologous donors. Donor rats were of approximately the same age as the recipient animals.

Table 1. BONE MARROW PROTECTION OF RATS AGAINST A LETHAL DOSE (7·5 MGM./KGM.) OF 2 : 5-DIMETHANESULPHONOXYHEXANE (*CB* 2348)

Exp. No.	No. of donors per recipient	Route	Interval between chemical and bone marrow injection (hr.)	No. of animals surviving*	Strain of donors†	Strain of recipients†
1	1	I.V.	4	0/5	*W*	*W* (1)
2	1	I.V.	3	3/4	*A*	*A* (2)
3	1	I.V.	3	2/2	*A*	*A*
4	1	I.P.	3	4/5	*A*	*A*
5	4/5	I.P.	3	0/5	*A*	*A*
6	1	I.P.	3	3/4	*A*	*A*
7	2	I.P.	3	5/5	*A*	*A*
8	2	I.P.	1½	4/5	*A*	*A*
9	2	I.P.	24	1/5	*A*	*A*
10	2	I.P.	48	0/5	*A*	*A*
11	2	I.P.	96	0/5	*A*	*A*
12	2	I.P.	2	0/10	*M*	*A* (3)

* There were five control animals in each experiment, all of which died in 10–14 days.

† *A* = August; *W* = Wistar; *M* = Marshall.

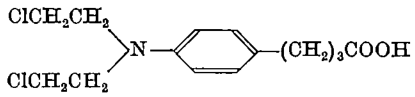
(1) Wistar → Wistar = homologous; (2) August → August = isologous; (3) Marshall → August = homologous.

The results from representative experiments are summarized in Table 1.

It is thus clear that in the majority of our experiments the lethal effects of *CB* 2348 can be largely overcome by intraperitoneal or intravenous injections of isologous bone marrow. Homologous marrow was ineffective, and attempts to protect Wistar rats were unsuccessful. It was possible to achieve protection by bone marrow injection at 1½–24 hr. after the chemical was administered, but not at 48 hr.

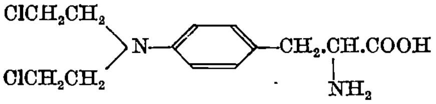
In collaboration with Dr. L. F. Lamerton and Dr. J. M. Loiselle, we have also completed a series of experiments in which August rats were exposed to 500 or 550 r. of X-radiation, followed, in ½–3 hr., by injections of isologous or homologous bone marrow. These amounts of irradiation caused death of the control animals at about 12–16 days. Isologous marrow, but not homologous marrow, was effective in preventing death in almost all animals.

There is considerable evidence that lymphatic tissue plays an important part in the development of immune responses[15]. Myleran suppresses the hæmatopoietic elements more than the lymphatic tissues. Nitrogen mustard (*HN*2) and related compounds such as chlorambucil:



have a relatively greater effect on lymphatic tissue, and their action on the other hæmatopoietic activity is of shorter duration than myleran. *CB* 2348 lies somewhere between these two compounds in its mode of action[4,5].

One would therefore expect that the nitrogen mustard derivatives would behave like X-radiation with respect to suppression of immune responses, and that if protection against the lethal effects of nitrogen mustards could be accomplished it could be achieved by the injection of either isologous or homologous bone marrow. However, the response of most animals to toxic doses of these chemicals follows one of three patterns, depending upon the dose administered: (*a*) acute convulsive seizures and death within a few hours; (*b*) death within 3–7 days in a manner similar to that which follows supralethal doses of X-radiation; or (*c*) weight-loss, diarrhœa and pancytopenia followed by rapid recovery[16]. The response described in category (*b*) is usually elicited by amounts in the range of the median lethal dose, but it is difficult to plan an experiment in such a way that death is produced in the majority of animals at 6–7 days. Chlorambucil, one of the aromatic nitrogen mustards, closely resembles *HN*2 in these patterns of response at different doses. It thus appears likely that in order adequately to suppress the immune response of rats by means of *HN*2 or related compounds, a dose must be given which leads to death in the same fashion as in (*a*) or (*b*) above. The nitrogen mustard derivatives of an aromatic amino-acid, such as melphalan (*CB* 3025):



do not produce acute death or convulsions as in category (*a*), even at more than twice the lethal dose, and there is evidence to suggest that deaths in category (*b*) above will be somewhat more delayed than with other nitrogen mustard derivatives tested so far. Protection experiments are therefore being conducted with this and similar compounds in an effort to define further the potentialities and mode of action of some of the chemotherapeutic or alkylating agents.

METAL-CHELATING PROPERTIES OF PLANT-GROWTH SUBSTANCES

By DAN COHEN and BEN-ZION GINZBURG

Botany Department

AND

DR. CARLA HEITNER-WIRGUIN

Inorganic Chemistry Department, The Hebrew University, Jerusalem

IT has been found that several chelating compounds have auxin activity[1–4]. As a consequence, it has been suggested that the activity of the known auxins is due to their chelating action[1,2].

Auxin action has been ascribed to the two-point attachment of the growth substance to some suitable substrate, the attaching groups being the aromatic ring and a polar group of the side chain[5,6]. The complexing groups of a bidentate chelate may serve as such points of attachment. However, no chelating action has been reported for indolyl-3-acetic acid or α-naphthalene acetic acid. The chelating activity of these acids was therefore investigated.

The methods used were those described by Martell and Calvin[7]. As the auxins are only slightly soluble in water, they were dissolved in 50 per cent ethanol, which also was a suitable solvent for the metal salts. Absorption spectra of indolyl-3-acetic and α-naphthalene acetic acids and cupric nitrate were determined, using a Beckman *DU* spectrophotometer. The results are given in Fig. 1. A pronounced difference is observed when the spectrum of the mixture of the auxin and copper salt is compared with the sum of the two separate spectra. This indicates a change in chemical bonding which can be interpreted as chelating or complexing of the metal by the acids. The composition of the complex was determined by plotting absorption of the copper–indolyl-3-acetic acid complex at 360 mμ and that of the copper–α-naphthalene acetic acid at 330 mμ against the ratio acid/copper in both cases, keeping the acid concentration constant (Fig. 2). Breaks in the curves indicate the composition of the complexes in the solution; such breaks were obtained at 1 copper : 1 indolyl-3-acetic acid; 1 copper : 2 indolyl-3-acetic acid and 1 copper : 2 α-naphthalene acetic acid. The stability of the complexes was determined by the Bjerrum method, as modified by Calvin[7] to suit the MA_2 case. *p*H titration curves for free acid and acid with small amount of metal were plotted (Fig. 3). The horizontal distance between the curves is equivalent to the amount of hydrogen ions released by the complexing of the metal.

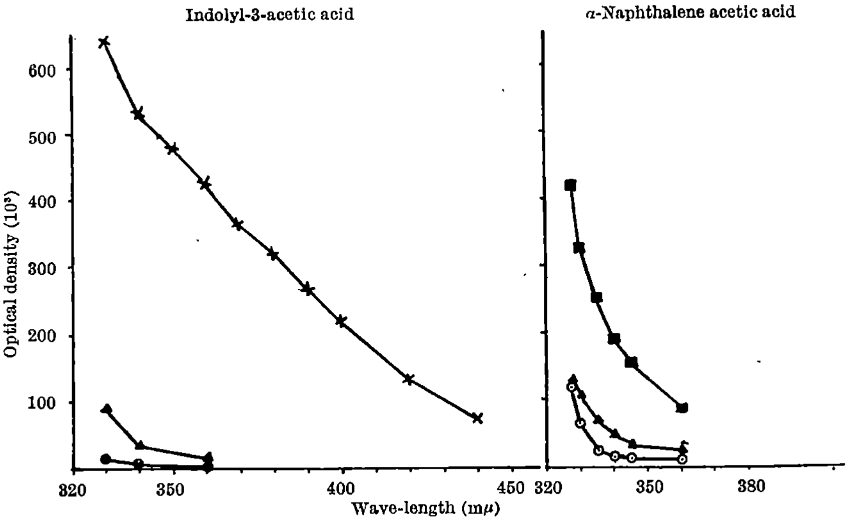

Fig. 1. Absorption spectra in 50 per cent ethanol. *p*H 3·6. ⊗, indolyl-3-acetic acid, 2 × 10^{-2} *M*; ▲, $Cu(NO_3)_2$ 3 × 10^{-3} *M*; ×, indolyl-3-acetic acid 2 × 10^{-2} *M* + $Cu(NO_3)_2$ 3 × 10^{-3} *M*; ⊙, α-naphthalene acetic acid 2 × 10^{-3} *M*; ▲, $Cu(NO_3)_2$ 2 × 10^{-3} *M*; ■, α-naphthalene acetic acid 2 × 10^{-2} *M* + $Cu(NO_3)_2$ 2 × 10^{-3} *M*

Concentration of acids constant at 2×10^{-2} *M*. ×, copper–indolyl acetic acid complex; +, copper–α-naphthalene acetic acid complex

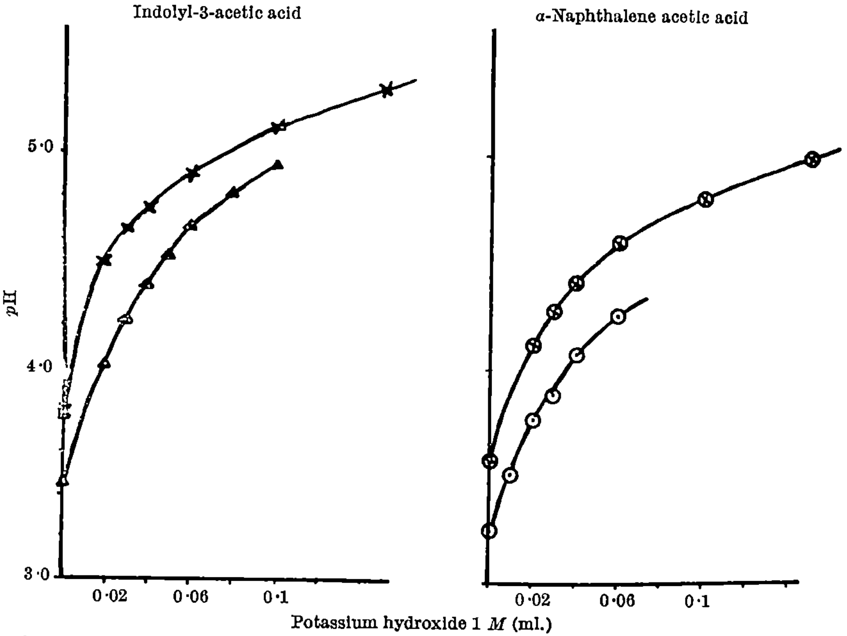

Fig. 3. pH titration curve in 50 per cent ethanol. ×, indolyl-3-acetic acid; ⊗, α-naphthalene acetic acid; ▲, indolyl-3-acetic acid + $Cu(NO_3)_2$; ⊙, α-naphthalene acetic acid + $Cu(NO_3)_2$. Concentration of acid, 10^{-1} *M*. Concentration of $Cu(NO_3)_2$, 2×10^{-3} *M*. Titration with *M* potassium hydroxide

From these titrations the degree of formation $\bar{n}$ was calculated and plotted against $-\log$ [indolyl-3-acetic acid$^-$] and $-\log$ [α-naphthalene acetic acid$^-$], respectively. The calculated stability constants for the overall reaction were: $\log K = 5{\cdot}4$ for copper (α-naphthalene acetic acid)$_2$ ($\log k_1 = 3{\cdot}2$; $\log k_2 = 2{\cdot}2$); $\log K = 5{\cdot}5$ for copper (indolyl acetic acid)$_2$ ($\log k_1 = 3{\cdot}2$; $\log k_2 = 2{\cdot}3$).

Under the same conditions indole showed only very slight complexing ability. Roberts, quoted by Heath and Clark[1], suggested that indolyl-3-acetic acid could chelate between the carboxyl oxygen and the imino nitrogen, forming a seven-membered ring. α-Naphthalene acetic acid, however, lacks a replaceable hydrogen on a basic atom in the ring. As both copper (indolyl-3-acetic acid)$_2$ and copper (α-naphthalene acetic acid)$_2$ compounds show similar stability, another mechanism of chelating activity must be applied to suit both compounds. The first complexing group is the carboxyl group, the properties of which are probably not affected by these substitutions in the acetic acid molecule, since the *pKa* acetic acid is 4·7, indolyl-3-acetic acid is 4·6 and α-naphthalene acetic acid is 4·6. The complexing action of the carboxyl group in acetic acid is low with copper ions. As the second complexing group the entire aromatic ring may function. There is some evidence for this in the recent finding of complex formation between metal ions and various aromatic compounds[8,9]. This explanation of the second active site could apply both to α-naphthalene acetic and indolyl-3-acetic acids, and could be the basis of the two-point attachment theory for auxin activity.

Some other preliminary experiments with indolyl-3-acetic acid show strong chelating activity with ferric ions and considerably less with cobaltous ions ($\log K \sim 2$). No activity could be demonstrated with calcium and magnesium ions. Consequently, if the growth-promoting activity of auxin is due to its chelating property, this could be only with heavy metals. There are several possible modes of action of auxin as a heavy-metal chelating agent. It may act as a carrier, mask functional heavy-metal ions, or remove ions inhibitory to cell wall growth.

Our thanks are due to Prof. Patai, of the Organic Chemistry Department of the Hebrew University, and Dr. J. Edelman, of the Imperial College of Science and Technology, London, for helpful criticism and stimulating discussion.

Radio Noise from Lightning Discharges

In studies of atmospheric radio noise from thunderstorms, and of its interference with radio systems, it is useful to know the wave-forms of the atmospherics received in different frequency bands from a single lightning discharge. Although measurements of the electromagnetic field changes are the basis of much of our knowledge of the discharge processes, they have been mainly restricted to frequencies less than 100 kc./s. Norinder[1] has recorded samples of noise at 500 kc./s., but there are few records of the wave-forms of atmospherics in the high-frequency band which is important for long-distance communication. Records obtained at the Radio Research Station, Slough, during two local thunderstorms are therefore of interest both in the study of radio interference and also as a possible source of further information about the discharge processes.

During a storm on July 19, 1957, records of the wave-form of the vertical component of electric field were obtained, in a bandwidth of 300 c./s. at 11 Mc./s., from twenty-five flashes at known distances in the range 1–6 km., deduced from the delay in hearing thunder. Twenty-one flashes were seen to strike the ground; the others may have been either cloud flashes or ground flashes obscured from view.

The atmospherics were recorded on magnetic tape, at a subcarrier frequency of 10 kc./s., and later transferred to film. The wave-forms were so varied in detail that it was difficult to select any as being typical, but those reproduced in Fig. 1 illustrate the main features. Fig. 1*a* shows a single relatively large burst in an atmospheric of total duration 230 m.sec. In Fig. 1*b* the whole atmospheric is of similar duration but contains several peaks of comparable amplitude. Fig. 1*c* shows a more continuous type of atmospheric with the largest amplitude at the beginning. These atmospherics, all from ground flashes at distances of about 3 km., had peak amplitude in the range 550–900 μV./m., and the amplitudes of all twenty-five atmospherics were of this order. The durations were in the range 40–330 m.sec.

Fig. 1*d* is a record from a flash at 5-km. range which was seen to be in the form of a catenary, well above the ground, with its ends in the thundercloud. So far as could be seen, neither the amplitude nor the wave-form was significantly different from those originating in ground flashes. Although the flash appeared to be of the cloud type, it may have struck the ground outside visible range.

The suggestion has been made[2] that noise in the high-frequency band originates in the stepped-leader type of discharge which travels towards the ground and is usually followed by a high-current return stroke from the ground to the cloud. The stepped-leader part of the discharge lasts only for a time of the order of a millisecond, however, and cannot be responsible for the relatively long bursts of noise in the examples shown.

A study of the high-frequency atmospheric in relation to that recorded at very low frequencies is instructive, since a very-low-frequency atmospheric is known to contain large pulses originating in the return strokes. During another storm, on August 12, 1957, noise fields were recorded simultaneously at 11 Mc./s. and 6 kc./s., in band-widths of 300 and 200 c./s. respectively. A twin-track recorder was not available, and the two frequencies were recorded on a single track, the 6 kc./s. signal direct and the 11 Mc./s. signal after frequency-changing to 10 kc./s. The tape was then played back, through low- and high-pass filters to separate the signals, on to a two-gun cathode-ray tube for obtaining film records.

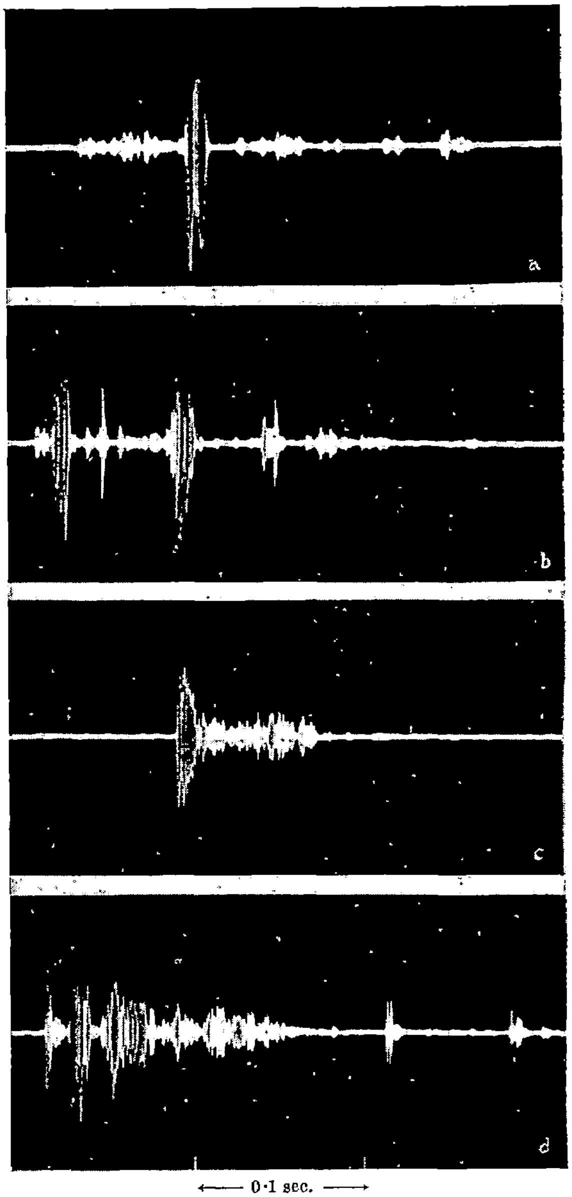

Fig. 1. 11 Mc./s. atmospherics from near storm

Most of the flashes were outside visual range (about 10 km.); only three were seen to be ground flashes, but there were no doubt many others.

The wave-forms were generally similar to those from the earlier storm, but again with a wide variation in detail. Twenty-six records from flashes at known distances between 1 and 18 km. were examined. The high-frequency atmospherics had

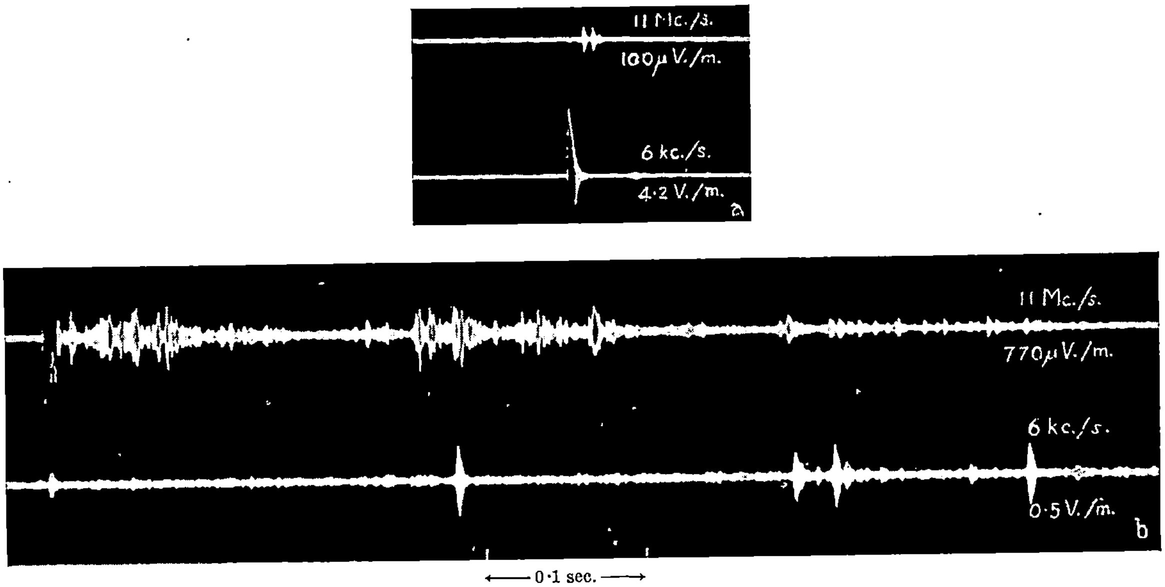

Fig. 2. Corresponding atmospherics at 11 Mc./s. and 6 kc./s.

peak amplitudes between 50 and 1,500 μV./m. and those at very low frequency between 0·3 and 30 V./m. Seventeen of the atmospherics had a ratio of very-low to high-frequency peak amplitude of 10^4, within a factor of 2 either way, but the total range was 650–42,000. Fig. 2*a* shows the atmospheric with the highest ratio and Fig. 2*b* that with the lowest. It should be noted that each record has been adjusted in amplitude to illustrate the main features clearly, and the scale therefore varies from one record to another. The absence of large pulses in the 6 kc./s. record of Fig. 2*b* may be an indication that it was a cloud flash.

Fig. 2*a* illustrates a curious phenomenon which occurred on many of the records. The main feature of the high-frequency noise was the pair of pulses, the first of which occurred about ten milliseconds after the very-low-frequency pulse (presumed to originate in a return stroke). Of the twenty-six records examined, ten showed this double-pulse effect, while four others showed a single pulse in a similar position and two showed three pulses.

Fig. 3 shows atmospherics from the nearest ground flash, about 1 km. away. The first film record taken from the tape (Fig. 3*a*) could be interpreted, using the currently accepted model of the lightning flash, as indicating a flash with two, and possibly three, return strokes, the high-frequency noise being radiated from the preliminary discharges. Another record of the same atmospheric was taken from the tape, with much greater amplification at 6 kc./s. (Fig. 3*b*). A succession of very-low-frequency pulses was then observed with a wide range of amplitudes. Also the atmospherics were clearly seen to have started simultaneously and to have had the same overall durations on the two frequencies, characteristics which would probably not have been inferred from Fig. 3*a*.

Many of the features of these records are not readily explained in terms of our present knowledge of lightning, and a more detailed study of these and similar records may lead to new information about the discharge mechanism.

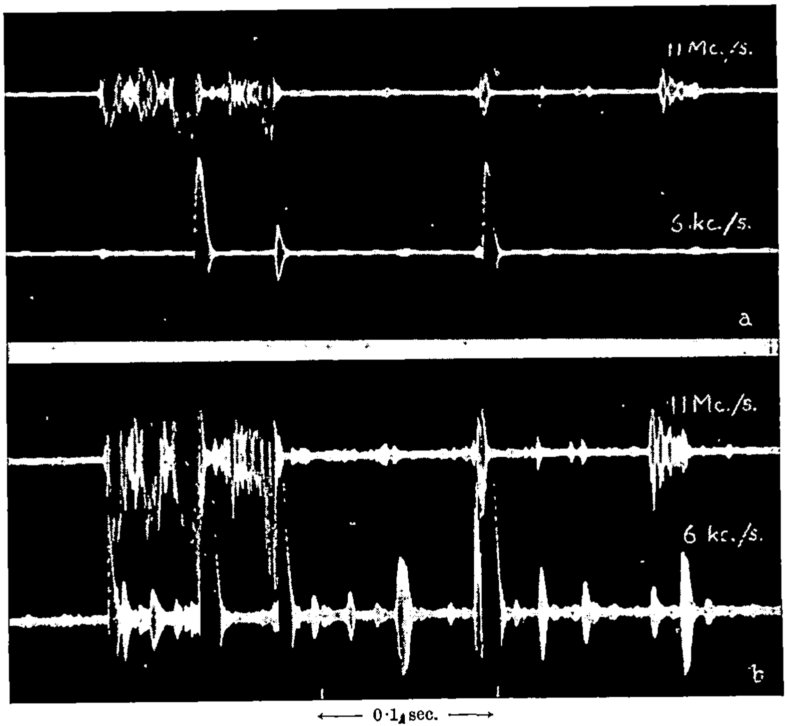

Fig. 3. Atmospherics from a very near flash. Peak amplitudes: 1·4 mV./m. at 11 Mc./s.; 30 V./m. at 6 kc./s.

Solar-Flare Effect in the F2-Layer of the Ionosphere

A solar flare usually causes a simultaneous increase in the electron density of the D- and E-layers of the ionosphere in the daylight hemisphere. It is rare, however, to find any corresponding increase in the $F2$-layer, and the only previously reported case occurred in 1949[1] during an important flare which was accompanied by an unusually intense burst of cosmic radiation.

A similar, but even more intense, flare occurred on February 23, 1956, and a simultaneous increase in $F2$-layer ionization at Okinawa has been reported by Shapley and Knecht[2]. Since increases of about the same magnitude occurred on other days, and since no simultaneous increases were observed at Adak, Baguio or Guam, Shapley and Knecht suggest that the increase at Okinawa may not have been caused by the flare.

The very great increase in D-layer ionization at Singapore during the flare of February 23, 1956, has already been described[3]. A simultaneous increase in the critical frequency (f) of the $F2$-layer was also observed but, since the behaviour of the $F2$-layer is notoriously erratic, a critical examination of the data is necessary to establish the validity of the obvious inference that the increase was caused by the flare. Fig. 1*a* shows the measured values of f on February 23, 1956, and a comparison curve based on the median values for the ten control days. Owing to the very high D-layer absorption during the flare, it was impossible to measure f at 1100 L.M.T., but a value has been estimated by extrapolating backwards from the measured values obtained between 1123 and 1200 L.M.T. A comparison between the two curves suggests that the values of f on February 23 were unusually high at 1100 L.M.T. and just afterwards. The visible flare began at about 1034, reached maximum intensity near 1045 and had almost vanished by 1200 L.M.T. There is, therefore, a *prima facie* case for suggesting that there is a correlation between the two events; but, to prove this, an objective method of measuring the frequency of occurrence and the magnitude of any other similar increases must first be found.

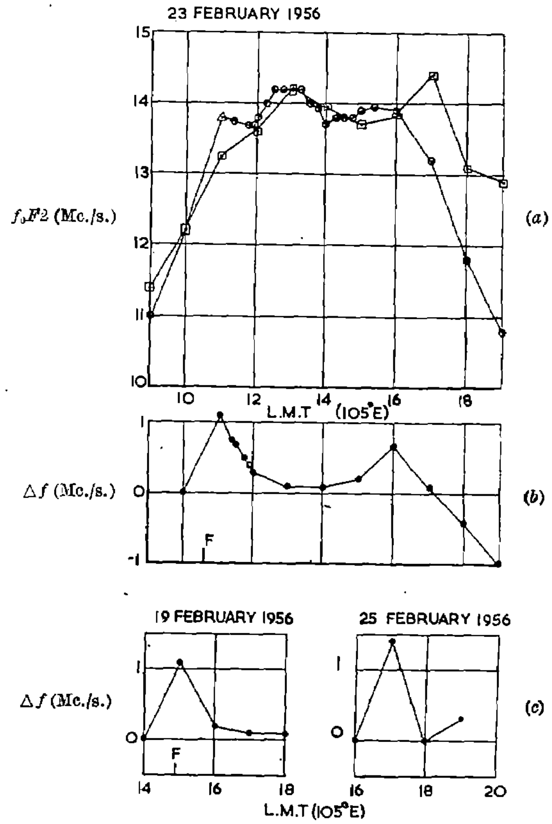

Fig. 1. Changes in f_0 (*a*) and Δf (*b*) for the $F2$-layer on February 23, 1956, and in Δf (*c*) on February 19 and 25, at Singapore. ⊙, Observed; △, extrapolated values; ⊡, 1·13 × median f_0F2 on control days February 18–28. F, commencement of flare

The measured critical frequency, $f_m(t)$, at time t (in hours) varies in an erratic manner from one day to another, but there is a close correlation between $f_m(t)$ and the value for the following hour, $f_m(t+1)$, on the same day. For each value of t, therefore, it is possible to fit a line through a series of points ($f_m(t)$, $f_m(t+1)$) obtained over a period of a few weeks; this has been done for each hour for the range of times t = 0900–1800 for the twenty-two day period February 14–March 6. For any given measured value of $f_m(t)$, the appropriate line may then be used to give the most probable value of f 1 hr. later: $f_p(t+1)$; the difference $\Delta f = f_m(t+1) - f_p(t+1)$ may then be used to represent the departure of the measured value from its 'normal' value. Fig. 1*b* shows the variations in Δf for February 23 using $f_m(1000)$ to derive $f_p(1100)$, $f_p(1100)$ to derive $f_p(1200)$ and so on. The presumed flare effect is seen to be a positive 'pulse' of amplitude 1·1 Mc./s. which is followed by a second smaller pulse at 1600 L.M.T. The same procedure was repeated for each of the twenty-two days mentioned above for t = 0900–1800; in addition to the two positive pulses on February 23, only two others were discovered which had amplitudes of 0·5 Mc./s. or greater. These occurred on February 19 and 25, and there was also a negative pulse of amplitude 0·5 Mc./s. on February 22.

An analysis of the statistics of the fluctuations in Δf has been made and from this it is possible to calculate the probability that a pulse exceeding any specified amplitude should occur by chance. From these calculations it follows that the second pulse on February 23 and the negative pulse might have occurred by chance. On the other hand, the number of pulses of amplitude not less than 1·1 Mc./s. expected to occur by chance during the twenty-two day period is 0·06, as compared with three pulses actually observed. It seems reasonable to conclude that the pulses on February 19 and 25 and the first pulse on February 23 are most unlikely to have occurred by chance and that some physical cause remains to be identified.

Table 1. Coincidence of Flares and Pulses

	Flare	No flare	Totals
Pulse	2	1	3
No pulse	14	181	195
Totals	16	182	198

The pulse on February 23 at 1100 L.M.T. was preceded by a class 2–3 flare which began at 1034 and and that on February 19 by a class 2 flare which began at 1455. No flare was observed during the hour preceding the pulse on February 25. During the period of 198 hours covered by the analysis, fourteen flares of class 2 or greater intensity were recorded which did not coincide with ionospheric pulses. These and other relevant data are included in Table 1. Since the 'expected' numbers in the two upper cells are small, the simple χ^2 test for significance cannot safely be used, but Yates's method gives $P = 0{\cdot}017$. The observed number of coincidences of flares and pulses (2) is greater than the number expected to occur by chance (0·24), and it is concluded that there is probably an association between the two phenomena.

The pulse on February 25 occurred during a severe geomagnetic disturbance and, since such disturbances are often accompanied by ionospheric disturbances, this may account for its having occurred in the absence of a flare. Although it appears that pulses of the type described can sometimes be caused by fairly intense flares, some additional factor must also be involved which is not always favourable and which permits the occurrence of pulses after only a small fraction of all such flares.

A New Thermal Image-Converter

A simple thermal image-converter can be made, using the dependence upon temperature of the absorption threshold in a semiconductor. When a sample of a suitable material is viewed by transmitted monochromatic light at a wave-length near the threshold, any variations in temperature appear as differences in the transmitted intensity. If a scene in which there are objects of various temperatures and emissivities is focused on the semiconductor, a visible picture will result.

The complete image-converter (Fig. 1) consists of a self-supporting film of amorphous selenium, metallized on one side, and mounted in a vacuum at the focus of a parabolic mirror. The film is viewed in transmission by light from a sodium lamp.

To achieve high sensitivity three requirements must be satisfied: (*a*) The semiconductor should have an extinction coefficient which is strongly dependent on temperature. This is determined by the product of two factors, the steepness of the absorption edge and the temperature coefficient of the forbidden energy gap. (*b*) The semiconductor must have low lateral heat spread; it must therefore be made as a thin film, and be of low thermal conductivity. (*c*) The film must be coupled strongly to the scene of view via the imaging mirror, and weakly to its surroundings.

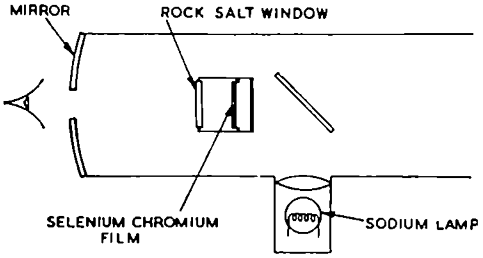

Fig. 1

For a simple tube it is also necessary that the absorption edge should be at a wave-length to which the eye is sensitive.

We have found amorphous selenium to be the most suitable semiconductor for the application. It has a thermal conductivity[1] less than 5×10^{-4} cal./gm. and can easily be prepared as a thin self-supporting film. At 5890 A. its extinction coefficient is $1{\cdot}7 \times 10^4$ cm.$^{-1}$, with a temperature coefficient[2] of 190 cm.$^{-1}$ deg.$^{-1}$. The energy gap changes by $9{\cdot}7 \times 10^{-4}$ eV. deg.$^{-1}$. The edge is not as steep as in semiconductors such as germanium and silicon, but the large change of energy gap with temperature more than compensates for this.

Since, like most semiconductors, selenium is transparent to thermal radiation, some absorbing layer must be added to the film. It has been shown elsewhere[3] that a composite metal–selenium film has a high absorption for radiation incident on the selenium side at angles of incidence less than 50°, but low absorption for larger angles of incidence, or for radiation incident on the metallized side. Its average emissivity will therefore be quite low.

The last requirement is therefore met by using a selenium–metal combination in an enclosure, evacuated to eliminate convective losses, with the selenium side facing a mirror of high aperture ratio. The selenium should be about 1μ thick, but the sensitivity is not strongly dependent on the nature or thickness of the metal.

Using an absorption-edge tube of this nature, with an *f*/1 parabolic mirror, objects 15 deg. C. above ambient temperature can be seen. Fig. 2*a* shows the image of a kettle 60 deg. C. above ambient. The sensitivity limit is determined by the smallest contrast which the eye can detect. Fig. 2*b* shows the image of a head. In this photograph the contrast has been doubled by a photographic technique.

The resolution obtained is 2 line-pairs per mm. and is probably equally limited by the performance of the mirror and of the film. The time-constant is less than 0·5 sec., and an exposure of 2 sec. is sufficient to photograph the image.

For objects hotter than 200° C. the aperture of the mirror must be reduced to avoid crystallization of the selenium. Crude sealed-off tubes have been made in which the two windows are waxed to the glass, and the vacuum required (10^{-4} mm. of mercury)

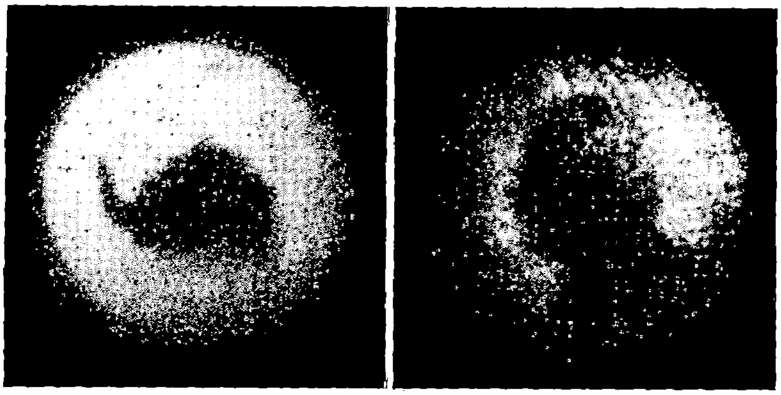

Fig. 2

maintained by getters. The life before re-pumping was needed was about two months. If longer life is required it is necessary to use a more complicated rock-salt-to-glass seal[4] and to out-gas the tube. The film must be kept cool during this process.

We are grateful to the Admiralty for permission to publish this communication.

Stress Optical Coefficients of Different Specimens of Vitreous Silica

In a recent communication[1] the results obtained from a study of the stress optical coefficient of a sample of vitreous silica and its variation with wave-length were described. This sample was obtained from the Thermal Syndicate, Ltd., England, a few years ago. In order to find out whether there was any variation of stress optical coefficient from specimen to specimen, two specimens of vitreous silica one of '*OH*' quality and the other of '*OG*' quality were recently obtained from the same firm. Each specimen was in the form of a rectangular plate (20 mm. × 20 mm. × 5 mm.) with polished faces. Using the same experimental technique as before[1], accurate determinations have been made of the stress-optical coefficient, *C*, of these two samples over the wave-length range 2300 A.–5400 A. Measurements were made for not less than 25 different wave-lengths well distributed throughout the range investigated. The variation of *C* with wave-length for the two new specimens is represented graphically in Fig. 1. The errors in the value of *C* for the various wave-lengths for the '*OH*' and '*OG*' quality specimens are less than 0·5 per cent. The values obtained for the earlier specimen are shown as curve *P* in Fig. 1. It is seen that for any wave-length the stress optical coefficient *C* for the '*OH*' quality specimen is less than that for the '*OG*' quality, the difference being of the order 2 per cent. It is found that dispersion for all these specimens remains practically the same.

The '*OH*' quality was irradiated by neutrons in the APSARA reactor (Trombay) by the courtesy of the Indian Atomic Energy Commission. The integrated neutron flux hours were 47×10^{11} neutrons/cm.^{2}. The specimen was coloured violet-brown after irradiation. The variation of *C* with wave-length for the irradiated specimen is represented by the broken curve in Fig. 1. It is found that neutron irradiation increases the value of the stress optical coefficient. At 5000 A. the increase amounts to 1·7 per cent, while at 2500 A. it is about 2·9 per cent. The trend of the curve for the neutron-irradiated specimen appears to be different from that of '*OG*' quality.

The colour of the neutron-irradiated specimen was partly bleached by exposure for about twelve hours to ultra-violet radiation (λ 2536). The resulting specimen did not exhibit any appreciable variation of the stress optical coefficient from the unbleached specimen.

Thus it is seen that the observed values of *C* for any particular wave-length are different for different specimens of fused quartz. This could only be due to three factors, namely, the variation from specimen to specimen of (1) refractive index, (2) homogeneity and (3) impurity.

According to the Thermal Syndicate, the difference between '*OG*' and '*OH*' quality lies only in the homogeneity of the specimens—'*OH*' being more homogeneous than '*OG*'—and not in a difference in the impurity content. The specimen employed in our earlier investigation[1] is less homogeneous than the present '*OG*' quality. Besides, the variation in refractive index between '*OG*' and '*OH*' quality is of the order of two units in the fourth decimal place. This cannot account for the observed difference in the variation of *C*. Therefore the difference in the stress optical coefficients of the specimens must be due to the variation in the homogeneity of the different specimens. An improvement in the homogeneity decreases the value of *C* for any particular wave-length and vice versa.

Intense neutron irradiation changes the refractive index of fused silica slightly[2]. For the neutron dosage employed here, the change in the refractive index will be too small to account for the observed effect on the stress optical coefficient. It is possible

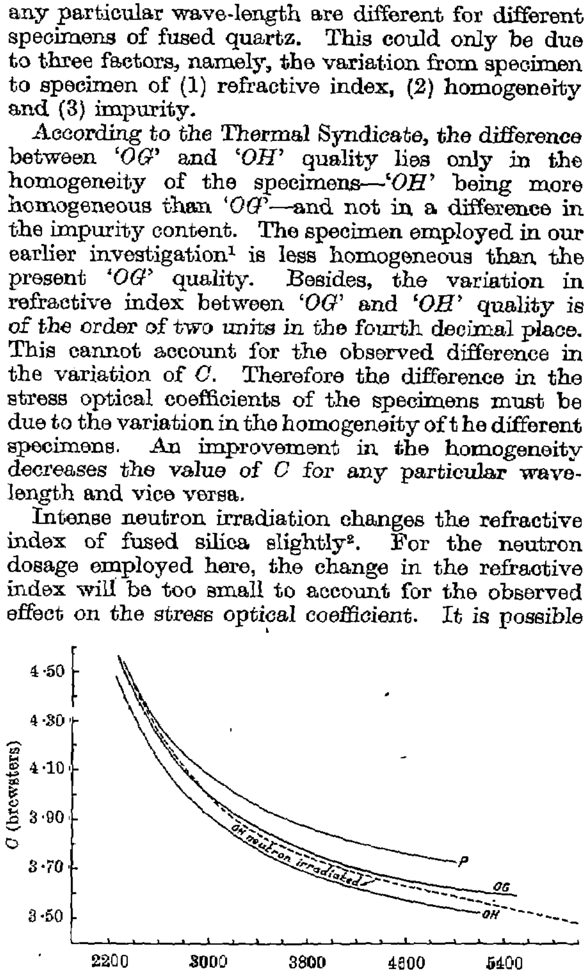

Fig. 1. The stress optical coefficient of different specimens of vitreous silica. *P*, previous sample

that neutron irradiation causes a decrease in the homogeneity of the '*OH*' quality specimen and this might explain the increase in the stress optical co-efficient following irradiation.

We wish to thank Dr. G. E. Stephenson, of the Thermal Syndicate, Ltd., for the information concerning the refractive index and homogeneity of the specimens, and the Indian Atomic Energy Commission for the neutron irradiation.

An Improved Orientation Stage for Microscopic Optical Crystallography

A PRELIMINARY description has been published[1] of an accessory to the polarizing microscope embodying novel principles which allow a full range of optical qualitative studies, quantitative measurements, and refractive index determinations to be carried out simply and accurately on diverse crystalline material such as well-developed crystal individuals, fragments, and sectioned aggregates. The crystal occupies the centre of a glass sphere, formed of two easily detachable segments, which has complete freedom of rotation about its centre, thus allowing the conoscopic or orthoscopic phenomena to be observed for any desired direction of transmission within the crystal. Morphological and optical data representing axial or planar directions within the crystal, as, for example, the optic axes, are adjusted to the cross-hairs and recorded by an automatic plotting device in their equivalent positions on the outer surface of the sphere. Simple great circle and polar relationships only are involved, and the angular data plotted upon the surface of the sphere is measured on a vernier to one-tenth of a degree, on the periphery of a single horizontal graduated circle.

Owing to refraction by the glass of the sphere, however, quantitative data so plotted are subject to correction and re-plotting to yield the true undeviated direction and angular values within the crystal. The necessity for this correction has been now successfully overcome by a modification of the sphere, described below, which greatly simplifies procedure.

In the original design, a given ray, traversing the crystal, is refracted upon meeting the plane surface of the upper segment, the direction of the new path depending on both the angle the ray makes with the normal to this plane surface, and the difference between the refractive index of the given ray and that of the glass.

The purpose of the new sphere design is to eliminate deviation and the need for correction, and this is accomplished by providing the upper segment with a small hemispherical hollow truly concentric with the outer spherical surface of the segment. Provided the refractive index of the immersion liquid within the hollow and surrounding the crystal is equal to that for the transmitted ray within the crystal, the ray suffers no refraction, being always normal to the hollow spherical surface, and therefore points of emergence of optical directions recorded on the sphere occupy their true positions. The sphere, inscribed with the labelled directional data, becomes an accurate model of the crystal, depicting the optical indicatrix within its morphological scaffold. True cardinal directions are presented for principal refractive index observations by the immersion method, and the optical situation is clearly illustrated, facilitating complete determination of the specific characteristics of the crystal. In order to confine the immersion liquid to the centred grain under observation, independent of the attitude of the sphere, and also to facilitate the change of liquids in refractive index determinations, the upper segment is provided with a shallow annular trough surrounding the hollow, the resulting surface tension effects causing the preferential retention of the liquid at the centre, surrounding the crystal and filling the hollow. Only one sphere, of ordinary serviceable low refractive index glass, is needed to cover the whole range of crystal substances.

The advantage of the improved sphere is also applied to the projector for interference figures[2], and the phenomena observed by normal vision upon the screen occupy their undeviated positions, giving true readings for optic axial angles and other relationships.

The simplicity of operation of these instruments may extend the application of optical studies in fields where the complexity of other methods has been a hindrance. An experimental model of the orientation stage is being developed by Messrs. James Swift.

Triboelectricity and Electron Traps in Insulating Materials : Some Correlations

THE contact electrification between metals has been explained by Harper[1] in terms of electron transfer due to the difference of work function of the metals, but the frictional charge on insulating materials is not so easily explained. Frenkel[2] has suggested that the friction develops high temperatures locally and instantaneously so that electrons in the full band in the insulators can be excited to the conduction band and may then be transferred and trapped in impurity levels on the surfaces. Vick[3] and Gonsalve[4] also postulated the existence of surface electron levels and assumed that the electron transfer between insulators is determined by the differences in energy of these levels[5]. Fowler[6,7] has investigated the detailed distribution of electron traps in a number of insulators by measuring the conductivity induced by X-rays. We have carried out the measurement of triboelectricity on the same materials that were used in the study of X-ray induced conductivity[6], in order to investigate the correlation, if any, between triboelectricity and the distribution of electron traps. These distributions had been derived from measurements of predominantly volume conductivity ; but the effects of surface traps could not be excluded.

The specimens were carefully cleaned with alcohol, and surface static charges were eliminated by the ionic atmosphere of a gas flame. Two specimens were rubbed lightly together and each rubbed surface was presented in turn to the measuring electrode,

PTFE = Polytetrafluoroethylene. PMMA = Polymethylmethacrylate.

which was connected to the grid of an $ET3$ electrometer triode in a bridge circuit. The measurement of absolute value of the charge was abandoned because of the different shapes of specimens. The signs of the surface charges were, however, readily determined, and the specimens could be placed in a well-defined triboelectric series as illustrated in Table 1. The positive or negative sign in Table 1 indicates that the material in the left-hand column is charged with that sign when rubbed against the material in the top line.

The order of the substances given in Table 1 by virtue of their triboelectric properties may be compared with the order of the same substances given in ref. 6 by virtue of the shape of the distribution of traps, where they were listed in order of progression from 'exponential' distributions of traps to 'uniform' distributions. The shape of distribution was defined by the parameter T_1 in the relation

$$M_E\, d_E = A\exp(-E/kT_1)\, \mathrm{d}E$$

where M_E is the number of traps between E and $E+\mathrm{d}E$ in depth (energy). When T_1 is small, approaching room temperature, the distribution will be steeply exponential. This is merely a formalized way of expressing the physical condition that there are many more shallow traps than deep ones, and it may apply only over a limited region of energy-depth.

Table 2 gives the values of T_1 for the substances listed in the same order as Table 1. In addition, a parameter E_x is given, representing an approximately exponential factor in change of conductivity with temperature when free electrons are being produced by X-rays. E_x was related to T_1 by the measured dependence of induced current upon X-ray intensity[6]. In addition, the total number of traps, M per cm.^{3}, is given: for the materials with low values of T_1 only a lower limit of M could be derived. While the correlation has some anomalies, particularly for unplasticized polymethylmethacrylate, it appears that in general the substances at the negative end of the triboelectric series are those with the largest values of T_1, that is, the most uniform distributions of traps and the smallest numbers of traps per cm.^{3}.

Table 2

Substances in order of triboelectric sign	T_1 (° K. × 10^3)	E_x (eV.)	M
Negative			
Polytetrafluoroethylene	0·58	0·5	10^{19}
Polyethylene	1·4	0·35	10^{19}
Polystyrene (United States)	0·9	0·18	10^{19}
Polystyrene (British)	0·5	0·44	10^{19}
Moulded amber	10	0·06	10^{15}
Natural amber	10	0·22	10^{16}
Polymethylmethacrylate (plasticized)	10	0·1	10^{16}
Polymethylmethacrylate (red)	4·3	0·07	10^{17}
Polymethylmethacrylate (unplasticized)	0·41	0·5	10^{19}
Mica	5·5	0·18	10^{16}
Positive			

It may be tentatively suggested that the partition of electrons between two substances is determined as follows: free electrons are produced when the substances are rubbed together, either by abrasion processes not yet understood or by local heating, and these free electrons are then shared between the traps of both substances, so that the substance with the greater number of traps below the Fermi limit will accept the greater number of electrons, becoming negatively charged. It would be expected that substances with an 'exponential' distribution, having a greater number of traps, should become negatively charged. The experimental evidence appears to confirm this expectation in general.

It should be emphasized that this conception is very crude and is only an attempt to explain the order of a particular triboelectric series from some previously determined trap distributions. The conception differs in detail from those mentioned in the introduction.

We wish to express our thanks to Dr. R. W. B. Stephens for his interest in this work and Dr. F. T. Farmer for providing the specimens. One of us (E. F.) expresses his appreciation to the British Council for granting him the scholarship during the tenure of which this work was carried out in the Department of Physics, Imperial College of Science and Technology, London.

Observation of Metal Sections by means of the 300-kV. Electron Microscope

Fernandez-Moran[1] has reported the preparation of ultra-thin sections of metal, and showed electron micrographs and diffraction patterns of sections of pure germanium used for transistors. He cuts the metal with the Moran ultra-microtome equipped with a diamond knife.

We have cut aluminium, copper and steel with an improved Minot-type microtome equipped with a Latta-Hartman type glass knife, and observed the

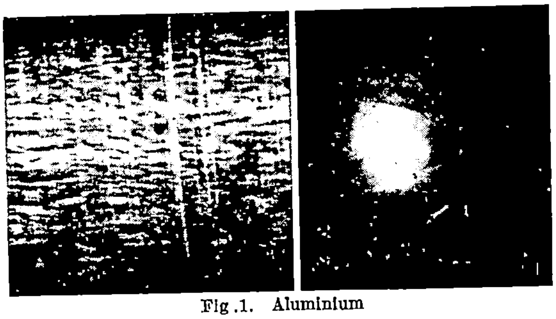

Fig. 1. Aluminium

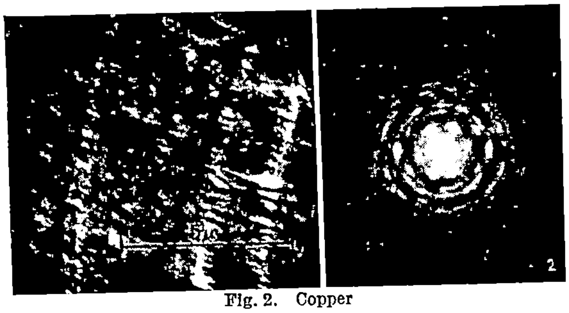

Fig. 2. Copper

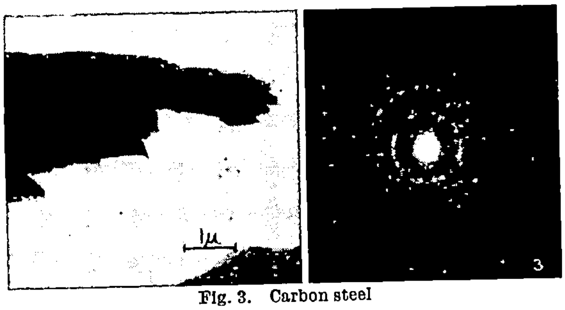

Fig. 3. Carbon steel

sections by means of the 300-kV. electron microscope[2]. The feeding mechanism of the microtome has been improved to give sections of 0·5 micron. The glass knife is set on the microtome with the cutting angle at about 50°–60°. The edge of a knife which has the cutting angle smaller than 50° is apt to be broken in the course of cutting. A relatively slow cutting speed is necessary to obtain sections. A small specimen of about 1 mm. × 1 mm. × 5 mm. is embedded in methacrylate resin to hold the specimen, and the sections are floated off the knife on the surface of 40 per cent ethanol or watchmakers' oil.

Even the 300-kV. electrons do not penetrate sections of 0·5 micron sufficiently, so the section is thinned by etching in hydrochloric acid or potassium cyanide. The etching may also serve to remove the residual strain in the sliced sections.

Fig. 1 shows the electron micrograph and diffraction pattern of a section of aluminium single crystal. Many lines and steps can be observed, which seem to correspond to the deformation of the crystal due to the non-uniformity or vibration of the knife edge. This fact is in contrast with the net-like diffraction pattern with Kikuchi patterns. Hence the section looks morphologically irregular in the electron micrograph, but crystallographically regular in the diffraction pattern.

Fig. 2 shows pictures of a section of copper. As in the case of aluminium, the diffraction pattern is from a relatively regular crystal, contrasting with the irregular shape in the electron micrograph. The diffraction pattern illustrates the oriented deformation of the crystal.

Fig. 3 shows pictures of a section of 0·1 per cent carbon steel. In this case the section is so thick that detail is not shown in the micrograph. The diffraction pattern, however, is clear enough to identify the specimen.

Rapid Assessment of Surface Radioactive Contamination

WHEN radioactive contamination occupies an extended area, as, for example, the surface of laboratory benches, its determination by the usual method of β-ray counting is tedious and is relatively not precise. However, the activity can be assessed in this case by a very simple, fast and sensitive method —the discharge of a conductor. The loss of charge of a conductor is due to the aerial ions of opposite sign generated by ionizing radiations, and the method of the discharge of a conductor has formerly been used for routine measurements of atmospheric conductivity[1]. I can give here only a very brief account of this method, which is based on the relation between the charge Q on a conductor and rate of loss of charge, given by Coulomb[2]:

$$dQ/dt = -aQ \qquad (1)$$

It can be easily shown that the constant a of Coulomb's equation is equal to $4\pi nw$, n being the number of ions per cm.^{3} of air surrounding the conductor and w their mobility in the electric field. From (1) we finally get the relation:

$$n = K/t \qquad (2)$$

where K is a constant implying the capacity constants of the measuring device, and t the time which corresponds to the drop of potential from V_0 to V_t. The validity of (2) supposes that V_0, V_t and w do not vary during the experiment, a condition practically always fulfilled for laboratory measurements.

When the ionizing radiation produces q ions of one sign per sec. per cm.^{3} then the total number of ions per cm.^{3} of air is given by the equation:

$$n = (q/\alpha)^{1/2} \qquad (3)$$

where α is the recombination coefficient for small ions, in our measurements a constant. The rate of ion-production q is proportional to the intensity J of ionizing radiation. When the source of this radiation is a radioisotope deposited on a plane surface with the activity A_0 per square cm. and the respective intensity of radiation J_0, we can put, according to (2):

$$t^{-1} \sim A_0^{1/2} \sim J_0^{1/2} \qquad (4)$$

The validity of (4) was tested with phosphorus-32 and strontium-90 + yttrium-90. A circular filter paper, with diameter 98 cm., was uniformly impregnated with the radioactive solution of which the activity was 33·8 μc. (4·48 × 10^{-3} μc./cm.^{2}) for phosphorus-32 and 59·3 μc. (7·85 × 10^{-3} μc./cm.^{2}) for strontium-90 and yttrium-90. The time t was determined for various distances x of the charged conductor from the active surface and the respective values of the

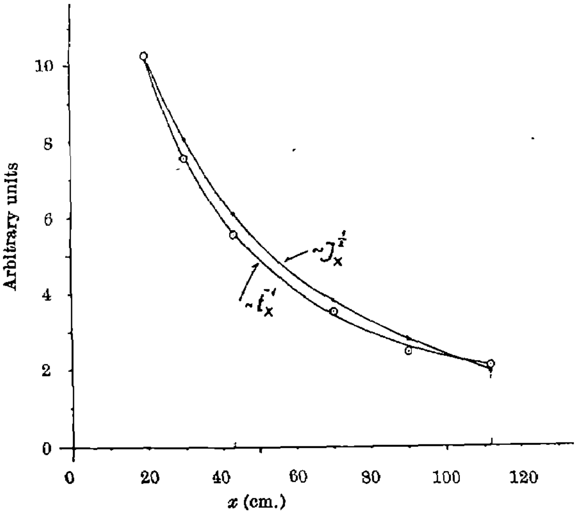

Fig. 1

intensity J_x of β-radiation were computed from the well-known absorption relation of King[3]:

$$J_x = -\tfrac{1}{2} J_0[Ei(-\mu x) - Ei(-\mu r)] \qquad (5)$$

In this equation μ is the absorption coefficient of the β-rays in air, x the minimum and r the maximum distance of the centre of the conductor from the active surface and Ei the exponential integral. Since the expression in front of the brackets in (5) is constant for a given experiment, J_x is determined by the difference of the two exponential integrals. The results obtained for phosphorus-32 are shown in Fig. 1. Within the limits of accuracy of this method (about 15 per cent) the curves reduced to the same origin agree very well. The parallel course of the two curves proves that the validity of (3) is not markedly impaired by the presence of large ions formed from the condensation nuclei. This fact is partly due to the weak electric field being unable to carry the large ions on the conductor to any considerable extent, and partly to the formation of these ions, governed by a relation similar to (3).

A simple measuring device has been used: the conductor, a piece of insulated aluminium wire (length about 9 cm., diam. 0·1 cm.), is screwed on the charging contact of a routine protection pocket electrometer of the stylo type. For current measurements the electrometer is supported by a very light wire frame in the form of two parallel letter X's connected by a cross wire. Sudden changes of the capacity of the exposed wire caused by the approach of a hand or a head to the microscope have no lasting effect on the reading of the electrometers. The fibre is deflected but returns immediately to its original position.

The conductor method is very sensitive because the measured value, n, varies with the square root of the activity. So for the previously mentioned sample of phosphorus-32 t had the value of 9·23 sec. for $x = 20$ cm., $V_0 = 145$ V. and $V_t = 120$ V. Since at the same time t for the natural background was about 1,200 sec., it is obvious that a specific activity as low as 10^{-4} μc. per cm.[2] can be easily detected. Analogous figures have been obtained for strontium-90 and yttrium-90, which suggests a simple method for the continuous registration of radioactive atmospheric fall-out from nuclear tests.

A detailed account of this work will be published elsewhere. I am indebted to Mr. Kočí, Mrs. Majerová and Mrs. Zelenková of the Institute of Nuclear Physics for their collaboration.

Electrical Discharges between Coaxial Electrodes

Luminous corona discharges occur when transient voltages, lasting about a microsecond, are applied between a wire and a small coaxially mounted ring in air. I have photographed these discharges and find that their shapes differ with the polarity of the electrodes. When the wire is made the negative electrode the discharge has the form of diffuse tufts, which are grouped around the wire into a roughly symmetrical brush; when positive, the discharge occurs in radial filaments (Figs. 1 and 2). Viewed along the axis the shape of a corona discharge resembles the Lichtenberg figure corresponding to the same polarity, which is produced by a discharge in air on an insulating surface between concentric electrodes[1] (Figs. 3 and 4).

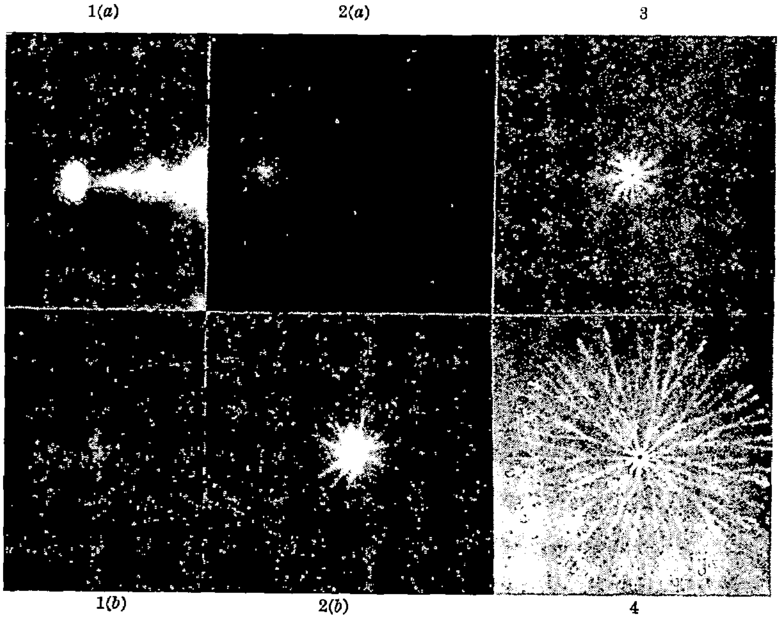

Fig. 1. Side views of wire: (a) negative, (b) positive. Fig. 2. Axial views of wire: (a) negative, (b) positive. Fig. 3. Lichtenberg figure, negative inner electrode. Fig. 4. Lichtenberg figure, positive inner electrode

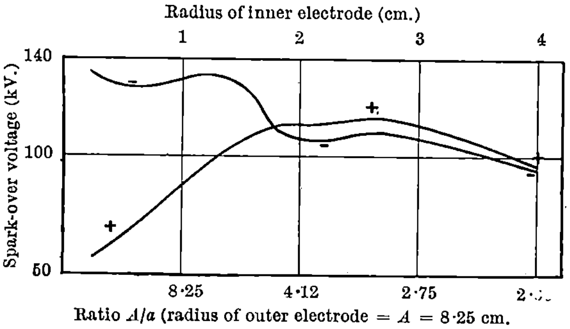

Fig. 5. Impulse spark-over voltage as a function of radius, *a*, of inner electrode

It appears from the photographs that the impulse corona forms a sheath around the negative wire, but has no such effect when the wire is positive. The form of the relation between wire-radius and impulse spark-over voltage in a system of coaxial cylinder and wire[2] (Fig. 5) is consistent with the assumption that a sheath, which protects the system against spark-over, is also formed in that geometry around the negative wire. The protection is greater than would be afforded by an extension of the wire-radius, which merely reduced the electric field; such an extension could raise the spark-over voltage no higher than the peak at $A/a = 3{\cdot}6$ (Fig. 5).

Differences of impulse spark-over voltage with polarity are observed not only in coaxial electrode-systems but also in many others, the value being almost always higher when the electrode at which the stress is greater has negative polarity[3]. It is surmised that protection of negative electrodes by impulse corona which precedes spark-over may be a general effect.

Distribution of Radioactivity in Rocks and Minerals, and the Effect of Weathering on Determinations of Uranium

In determining the uranium content of a series of rocks for the purpose of studying its geochemical behaviour, difficulties are often encountered because of the loss of uranium by leaching. In some cases it is almost impossible to ascertain whether or not a rock has been affected by leaching. Late-stage hydrothermal activity will remove (by solution) some uranium, but in addition to this a certain amount is removed by weathering. Because of the heterogenous distribution of uranium in acid rocks (for example, granites), the effect of hydrothermal solutions, mineralization and variations in uranium and thorium ratios, the geochemical behaviour of uranium is best approached by studying more homogeneous rocks, in particular basaltic types.

Adams[1] notes that the alpha-particle activity (as determined by scintillation counting) of a series of rocks when plotted against the uranium content gives rise to a linear plot. This indicates that the uranium–thorium ratio in the rocks studied was constant. In the Lassen Peak series studied by Adams, weathered rocks and mud flows did not show such a well-defined correlation of activity to uranium content. I have also observed (with a series of differentiated basic rocks, basalts, granophyres and granites) that a linear relationship exists between the uranium content of a rock and the alpha-particle activity (as determined by nuclear emulsion techniques). In the case of some basic rocks studied (uranium content, 0·05–1 p.p.m.) the uranium content of weathered samples is decreased by a factor of 30–50 per cent, but the linear relationship still holds. This indicates that some thorium was probably removed together with the uranium. In addition, there is apparently no separation of uranium and thorium towards the end of the differentiated series studied. This supports Adams's[1] view, and not those of Kirsch and Hecht[2], who believed that the process of differentiation would separate uranium and thorium. In order to undertake a more comprehensive study it is necessary to determine the total uranium and thorium content of weathered and unweathered samples. Unfortunately it is difficult to determine small amounts (< 10 p.p.m.) of thorium satisfactorily.

The distribution of radioactivity in the major rock-forming minerals has been fairly well established by Picciotto[3] and me[4]. There is no preferential increase of importance in the major minerals such as felspar, pyroxene olivine and quartz. Significant increases of radioactivity occur only in the accessory minerals such as zircon, epidote, orthite, sphene, xenotime, apatite and others. The distribution of radioactivity in intercrystal areas is very sporadic. A study of this intercrystal radioactivity is best approached by using nuclear emulsions; but even then it is possible that this loosely bound intercrystal material containing uranium and thorium may be partly removed during the preparation of thin rock sections. Another method of determining the easily leached radioactivity is by refluxing a rock sample with dilute acids, as described by Brown[5]. Great care must be exercised when carrying out such experiments, as radioactive minerals such as uraninite may be present. Deutsch[6] has described the presence of uraninite in the Baveno granite while I have observed it in the granites of Dartmoor and Shap.

While isolated intercrystal material containing radioactive elements may be totally removed by weathering by solutions percolating along cracks, this is not comparable to the weathering of such radioactive minerals as xenotime, monazite, uraninite, thorite, epidote, orthite and fergusonite. In the 'iron stain' halo surrounding these minerals it is observed that considerable amounts of radioactivity are present. On a smaller scale altered minerals often contain the bulk of the radioactivity on ferruginous secondary material. It is of interest to note that in the case of some preliminary studies carried out on the radioactive minerals of Norwegian pegmatites, the mineral may contain a certain percentage of uranium and thorium and be surrounded by a radioactive 'iron halo', while the surrounding felspar emits as much radioactivity as that present in the felspar of an oceanic basalt.

Finally, the distribution of radioactivity in a single mineral still involves a consideration of the radioactivity both within the body of the mineral and that present in cracks. Unfortunately, even with long exposures using nuclear emulsion techniques, it is difficult to determine these two factors on 'normal' zircons in a granite. Zircons are of particular interest as they are so widely used in age determinations. A study of zircons from Great Britain, Norway and Ceylon indicates the following.

(1) A zonal distribution of radioactivity in zoned specimens.

(2) Presence of highly radioactive point sources perhaps due to submicro inclusions of a very radioactive material or aggregates of radiocolloids.

(3) Either: (*a*) homogenous distribution of radioactivity; (*b*) increase of radioactivity in central areas of a crystal; (*c*) increase of radioactivity in peripheral regions.

(4) In zircons in particular as much as 50 per cent of the total radioactivity may be present in iron-stained intra-crystal cracks.

In conclusion, it has been observed that:

(1) A plot of total alpha-particle radioactivity against uranium content can indicate whether or not the uranium thorium ratio is constant, and the effect of weathering on the ratio.

(2) The radioactivity of the major rock-forming minerals is essentially constant.

(3) Weathering can lead to a loss of about 50 per cent of the total radioactivity and sometimes up to 50 per cent of the uranium content.

(4) The distribution of such rare accessory minerals as uraninite and thorite may be far more common than realized. The presence of such minerals prevents the determination of purely intercrystal radioactivity by acid-leaching studies.

(5) In some accessory and even major minerals appreciable amounts of radioactivity may be present in 'iron halos' surrounding the mineral and on cracks within the mineral. The radioactive material in such locations is easily leached.

Thermal Stability of Polytetrafluoroethylene

POLYTETRAFLUOROETHYLENE is notable among addition polymers for its high thermal stability. It decomposes at temperatures above about 400° C. to give tetrafluoroethylene as primary product[1]. It seems possible to account for this high stability in thermodynamic terms. A useful, though arbitrary, measure of the ultimate stability of a polymer, or more correctly of its free radical form, with respect to its monomeric precursor, is the temperature at which a particular pressure of monomer is supported over the polymer. This is given by[2]:

$$T_c' = \Delta H_{gc}/\Delta S_{gc}$$

where ΔH_{gc} and ΔS_{gc} are the heat and entropy of polymerization for the chosen monomer pressure at a suitable temperature, conveniently taken as 25° C. in most cases. Thus the ultimate stability is determined by the heat of polymerization of the monomer (which is in the range -16 to -25 kcal./mole for most monomers), and the entropy of polymerization (which increases with the molecular weight and complexity of the monomer). The heats of formation of tetrafluoroethylene and of its polymer (-152 kcal./mole[3] and -199 kcal./tetrafluoroethylene mole unit[4], respectively) give the heat of polymerization of tetrafluoroethylene as about -47 kcal./mole. The entropy of polymerization at 67° C. (which temperature is chosen to avoid anomalies resulting from the second-order phase transition of the polymer at room temperature), derived from the measured entropies of monomer[5] and polymer[6], is about -45 entropy units/mole for one atmosphere pressure of monomer. These compare with the values[7] $\Delta H_{gc} = -24 \cdot 7$ kcal./mole and $\Delta S_{gc} = -37$ e.u./mole for ethylene at 25° C., and account for the strikingly greater thermal stability of tetrafluoroethylene.

Thermochemical considerations suggest that other olefines containing the $=CF_2$ group will have heats of polymerization greater than those of better-known olefines, but lower than that of tetrafluoroethylene. The ultimate stabilities of polymers derived from these olefines will therefore be intermediate between those derived from normal olefines and from tetrafluoroethylene. In practice, however, the polymers may be less stable than these thermodynamic considerations suggest, since they may decompose more readily into other products. Examples are polyvinylidene fluoride and polytrifluoroethylene, which yield hydrogen fluoride as the first decomposition product[1].

Paper Chromatography of the Polycyclic Tar Hydrocarbons

WHATMAN No. 4 filter paper impregnated with 10 per cent paraffin oil, and methanol saturated with paraffin oil (prepared by shaking methanol with paraffin oil in a separating funnel) as the ascending mobile phase, were found suitable for paper chromatography of the polycyclic tar hydrocarbons (for others, see ref. 1).

The paper was impregnated by dipping it into a 10 per cent petrol–ether solution of paraffin oil, quality as in "Pharmacopoea Bohemoslovenica" (second edition), and by evaporating the petrol–ether during 15 min. The technique of paper chromatography employed is already adequately described[2]. After developing the chromatogram for about 4 hr. (30 cm. from the front to the starting point is sufficient), it was possible to see characteristic fluorescence spots under ultra-violet light.

The average R_F values and their colour under ultra-violet light, both of control substances and of

Carbohydrases in the Sugar-Gland Juice of *Cryptochiton* (Polyplacophora, Mollusca)

Although considerable work has been done on the digestive enzymes of snails and mussels[1], very little is known about those of the marine chitons. Fretter, working with the two British species, *Lepidochitona cinereus* Gray and *Acanthochitona crinitus* Gray, has reported[2] that the fluid in the sugar gland (a pouch-shaped organ connected with the œsophagus) hydrolyses starch, with a *p*H optimum at 5·6, and glycogen, with a *p*H optimum at 6·4–6·8.

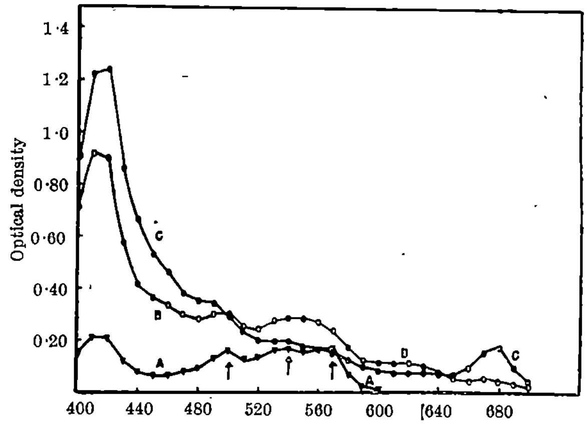

Fig. 1. Absorption spectra of different samples of *Cryptochiton* sugar-gland juice. The peaks indicated by the arrows (sample *A*) coincide exactly with those of phycoerythrin *R*. The peak at 680 mμ is probably caused by the presence of a chlorophyll

In 1956, we studied the enzymes in the sugar-gland juice of the giant chiton, *Cryptochiton stelleri* Middendorff, which is common along the Pacific coast of the United States. In most cases the juice, which can be obtained in considerable quantities, is salmon-coloured ; examination in the spectrophotometer reveals, very surprisingly, that phycoerythrin *R* is often present, while chlorophylls, such as chlorophyll *D*, may also occur (Fig. 1). The conclusion that the animal feeds largely on seaweeds is confirmed by the observation that large pieces of green, red and brown algae, including whole 'branches' of the hard coralline algae, can be found in the intestinal tract. A study of the mobilization of the algal carbohydrates by the chiton is imperative not only because of its intrinsic interest but also because of its ecological and biochemical implications.

Thus far, the following substrates were found to be hydrolysed energetically by the juice : starch, glycogen, laminarin, sodium-alginate, xylan from the red alga, *Rhodymenia palmata* ; cellulose and substituted celluloses, cellopentaose, cellotetraose, cellotriose, cellobiose, maltose, *iso*maltose, panose, turanose, salicin, α- and β-methyl glucoside, and melezytose. Agar is probably attacked by two enzymes in the juice ; one of these modifies the iodine reaction, whereas the other causes this reaction to disappear completely. Moreover, a drop in viscosity under the influence of the juice could be observed in very weak agar solutions after a few days. Weak or doubtful activity was displayed towards gentiobiose, fucoidin, tunicin and bacterial dextran ; no hydrolysis took place in the cases of sucrose, trehalose, lactose, melibiose, stachyose, raffinose and inulin. The *p*H optima for the hydrolytic actions were generally in the vicinity of *p*H 5 (Fig. 2), which is the natural *p*H of the sugar-gland juice ; cellulase, which seems to have a somewhat lower *p*H optimum (Fig. 3) forms an exception.

Thus α- as well as β-glucosidic 1 : 4 linkages between glucose residues (starch, glycogen, cellulose) and β 1 : 3 linkages between such residues (laminarin) can be broken. The evidence on α 1 : 6 linkages between glucose residues is less conclusive ; from the fact that *iso*maltose is hydrolysed with ease and that almost all the glucose theoretically expected is formed in the breakdown of starch (which has some 1 : 6 linkages) one must conclude that they are hydrolysed, but on the other hand the breakdown of bacterial dextran (which has an abundance of α 1 : 6 bonds) is very slow.

Some sugar-gland enzymes show synthetic as well as hydrolytic properties. For example, in digests with turanose, evidence was obtained for the transient occurrence of a new sugar with a slightly lower R_F value than turanose, and in *iso*maltose digests there were clear indications of trisaccharide formation.

The invulnerability of trehalose, sucrose and inulin is remarkable in view of the fact that these substances have been reported as constituents of blue-green algae (trehalose) and *Dasycladales* (sucrose, inulin), respectively. It is obvious that information on the activities of other parts of the digestive tract of *Cryptochiton* is needed. Most experiments were performed on the sugar-gland amylase, which was shown to be a true α-amylase, activated by halide ions (Fig. 4); it is able to digest native *Codium*-starch, and acts in conjunction with a powerful maltase. The *p*H optima for the breakdown of starch and of glycogen are identical. Some purification of the amylase could be achieved by procedures involving ammonium sulphate fractionation, adsorption on native potato starch and elution with weak ammonium phosphate solutions. The origin of the sugar-gland enzymes is not clear; they may be produced by symbiotic bacteria. It is possible that the activation of the amylase by halide ions may provide a clue, since it seems to be a general feature of the amylases of snails and bivalves, noticeable even in those cases where the presence of bacteria is at least doubtful.

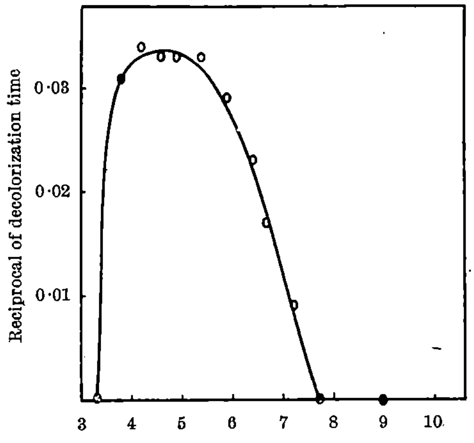

Fig. 2. *p*H optimum for *Cryptochiton* sugar-gland amylase. Activity studied by following the disappearance of the iodine reaction of a starch solution (Wohlgemuth method)

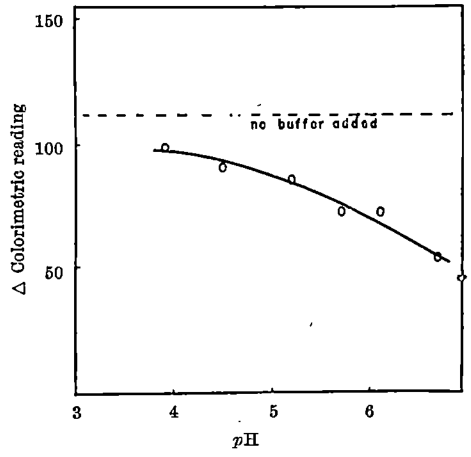

Fig. 3. *p*H optimum for the breakdown of cellulose by *Cryptochiton* sugar-gland enzyme. (Turbidity measurements on expanded cotton cellulose)

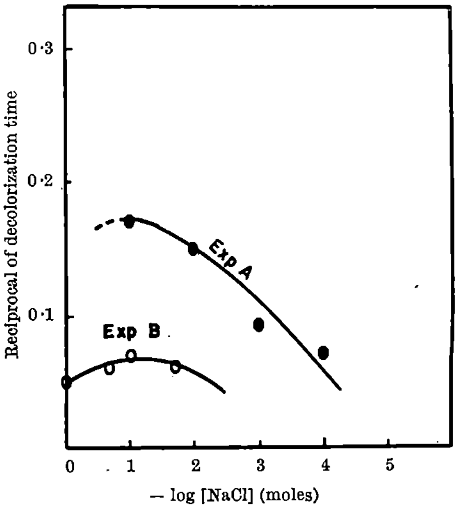

Fig. 4. Activation of *Cryptochiton* sugar-gland amylase by chloride ions

A systematic survey of the biochemical activities of the sugar gland is in progress.

Formation of β-Alanine from Spermine and Spermidine by *Pseudomonas aeruginosa*

THE importance of β-alanine, especially as a constituent of pantothenic acid, in biological systems is well recognized; but little is known about its biosynthesis. One possible mechanism of formation involves the decarboxylation of aspartic acid though this has been established only for a small number of bacteria[1]. It has been recently found that β-alanine might also be formed from uracil by a certain species of *Clostridium*[2].

Studying the degradation of the naturally occurring polyamines spermine and spermidine, we found that these substances were oxidized by *Pseudomonas aeruginosa*. Carbon dioxide and ammonia were evolved, and a ninhydrin-positive compound accumulated during the reaction. This compound behaved like β-alanine when analysed by paper chromatography using various solvent systems[3-5]. A similar result was obtained by paper electrophoresis, in phthalate buffer of *p*H 3·2[6].

The results are illustrated in Fig. 1; spermine (*a*) and spermidine (*b*) rapidly disappeared during the reaction, while β-alanine was formed. β-Alanine was then further metabolized by *Ps. aeruginosa*, as can be seen in all experiments. Quantitative measurement[8] showed that about twice the amount of β-alanine was formed from spermine compared to spermidine. This might be expected from the composition of the two compounds, since spermine

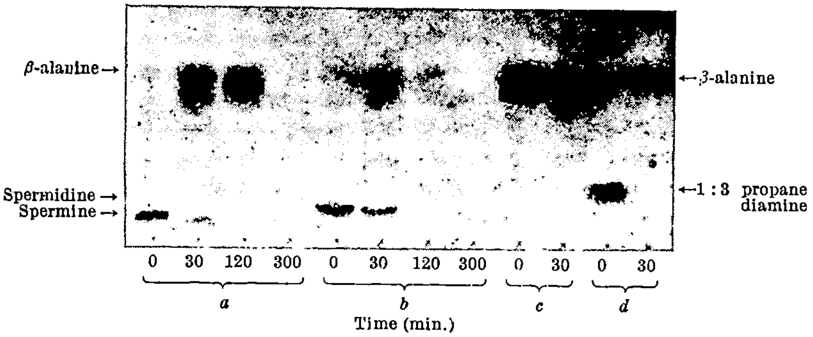

Fig. 1. Formation of β-alanine by resting cells of *Ps. aeruginosa*. Cells were grown on a semi-synthetic medium (ref. 7) enriched with 0·3 per cent spermine. Washed cells, suspended in 0·022 *M* phosphate buffer, *p*H 7·0, were incubated at 30° in Warburg flasks containing (*a*) 2·5 μ*M* spermine; (*b*) 2·5 μ*M* spermidine; (*c*) 5 μ*M* β-alanine or (*d*) 5 μ*M* 1 : 3 propane diamine, respectively. Samples were taken at the times indicated, centrifuged, and the supernatants analysed by paper chromatography (ref. 8)

contains two $(CH_2)_3$ fragments and spermidine only one:

$$NH_2(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH_2$$
spermine

$$NH_2(CH_2)_4NH(CH_2)_3NH_2$$
spermidine

That these $(CH_2)_3$ fragments participate in the formation of β-alanine, is borne out by the fact that 1 : 3 propane diamine was oxidized by *P. aeruginosa* to β-alanine, whereas putrescine was not.

The formation of β-alanine from spermine and spermidine thus opens up a new possibility for the biosynthesis of this important compound. This approach is especially attractive in view of the wide distribution of spermine and spermidine[9,10] and their role as growth-factors for various micro-organisms[11–13].

A detailed report of this study will be published elsewhere.

Substrate-Selective Inhibition of Mitochondrial Oxidations by Enhanced Tonicity

During an investigation of factors controlling rates of oxidation by mitochondria, it was found that variations of sucrose concentration in the suspending medium profoundly inhibited the oxygen consumption with some substrates but had much less effect with others. Earlier studies[1,2] have indicated that the use of 0·88 *M* sucrose as the diluent during homogenization and isolation of mitochondria resulted in lower rates of mitochondrial oxidations than when 0·25 *M* sucrose was used. This was true despite the dilution of the mitochondria with other components of the final reaction mixture.

In the present studies, rat-liver mitochondria were prepared in 0·25 *M* sucrose and 0·5 ml. of the washed suspension (equivalent to 0·5 gm. original liver) was placed in Warburg vessels containing, in 1 ml. of solution, 6 μmoles adenosine triphosphate, 50 μmoles inorganic phosphate, 15 μmoles magnesium sulphate, 50 μmoles glucose, 1 mgm. of partially purified yeast hexokinase and 20–40 μmoles of substrate. Final volume was brought to 3·0 ml. by the addition of sucrose solutions of appropriate concentration.

Typical experiments with each of ten different substrates are shown in Table 1. In our routine experiments the final sucrose concentration is 0·17 *M*. Lowering tonicity to 0·075 *M* sucrose seemed to have no adverse effect on either respiration or phosphorylation. However, raising the sucrose concentration above 0·17 *M* progressively inhibited the oxidation of glutamate, α-keto-glutarate, citrate, pyruvate (to aceto-acetate) and caprylate virtually to complete suppression at 0·48 *M*. Glutamate oxidation was 50 per cent inhibited at 0·37 *M* sucrose. It is interesting that oxidation of other pyridine-nucleotide linked substrates such as malate, *iso*citrate, proline[3] and β-hydroxybutyrate were much less inhibited. Succinate oxidation was relatively little affected.

It is possible that the selective effect with different substrates results from selective permeability of the mitochondria in higher concentrations of sucrose. Citrate must be oxidized via *iso*citrate, yet it is more strongly inhibited than the latter, indicating a selective permeability or an effect of high-sucrose on aconitase activity. Cooper and Lehninger[4] have reported high sucrose concentrations to inhibit dinitrophenol-stimulated adenosine triphosphatase and the exchange

Table 1

Substrate	Molarity of sucrose						Inhibition by hypertonicity (per cent)
	0·075		0·17		0·48		
	Q_{O_2}(N)	P/O	Q_{O_2}(N)	P/O	Q_{O_2}(N)	P/O	
Glutamate	35·8	2·8	31·5	2·7	0	—	100
α-Keto-glutarate	29·7	2·8	29·1	3·1	0	—	100
Pyruvate	18·1	2·7	19·0	3·1	0	—	100
Citrate	23·0	2·5	20·9	2·9	0·7	—	96

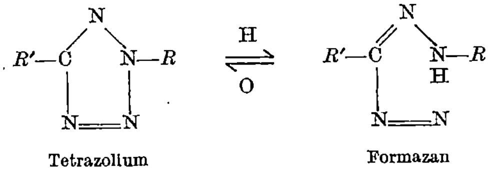
Cytochemical Localization of Succinic Dehydrogenase in Mitochondria from *Periplaneta americana*

Morphological[1,2] and biochemical[3-5] studies indicate that the mitochondrion is a structurally complex organelle in which certain oxidative enzyme systems are localized. The succinic dehydrogenase system, in particular, has been shown to be situated almost exclusively in the mitochondrial fraction of tissue homogenates.

Histochemical methods for showing this enzyme system depend on the acceptance of hydrogen by water-soluble tetrazolium salts and their reduction to coloured, insoluble, formazan dyes.



This reaction is not reversible in biological systems, and the amount of formazan deposited in tissue sections can be related directly to the amount of succinic dehydrogenase[6]. Localization of the succinic dehydrogenase system within the mitochondria is not possible, however, with the mono- and di-tetrazolium salts in current histochemical use. This is due partly to the slow rate at which they penetrate biological membranes and partly to the large crystal size of their formazans.

Recently, metal chelation of the formazans of mono-tetrazolium salts containing N-thiazol-2-yl groups has been successfully used for the intracellular localization of the succinic dehydrogenase system[7]. The present report concerns observations on the isolated mitochondria of the cockroach *Periplaneta americana* made during a series of experiments designed to evaluate the accuracy of localization of the succinic dehydrogenase system afforded by various metal-formazan complexes.

The pooled fat bodies of several cockroaches were homogenized in 0·44 M sucrose with a Potter–Elvehjem homogenizer and centrifuged at $800g$ for 10 min. The sediment was resuspended and washed once. The supernatants were centrifuged at $7,000g$ for 15 min., resuspended and washed twice. 2 ml. of a medium containing 3,5-diphenyl-2-(4,5-dimethylthiazol-2-yl) tetrazolium bromide[8], cobaltous chloride, various electrolytes, phosphate buffer at pH 6·3 and sodium succinate, was added to 1 ml. of a 10 per cent mitochondrial suspension in sucrose.

Details of the preparation of this medium have been published elsewhere[7]. The reaction in duplicate samples was completely inhibited by 1 ml. of 0·1 M iodoacetic acid added prior to incubation. The suspensions were incubated at 37·5° C. for 10–15 min. in an atmosphere of pure nitrogen. The reaction was stopped by the addition of 0·05 ml. of 10 per cent formalin and the suspensions were mounted in 10 per cent gelatin.

It was observed[7] that in thin fresh sections of tissues the metal chelation method did not reveal the mitochondria as they are usually shown by conventional staining methods but rather as rows of small black bodies. The present studies of isolated mitochondria show that each mitochondrion contains 2–5 of these 'bodies' the size of which depends to some extent on the length of incubation. They may appear (Fig. 1) as round objects 0·6–1·0μ in diameter. With longer incubation these can be seen to grow and finally to burst the mitochondrial membrane, an observation in keeping with the view that substrates must penetrate into the mitochondrion before being oxidized[9]. With short incubation times they appear (Fig. 2) in the form of straight or curved transverse bars, orientated at right angles to the long axis of the mitochondrion, the appearance of which suggests a relationship to the cristæ mitochondriales observed in electron microscope studies. Admittedly the characterization of these structures by the metal-formazan technique is much coarser. At higher magnifications (Fig. 3) further details of the 'cristæ' are revealed.

A composite tracing (Fig. 4) has been made of the localization of metal formazan at different levels in

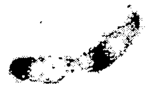


Fig. 1. Isolated cockroach mitochrondrion. Shows two round deposits of cobalt-formazan. (× 4,000)

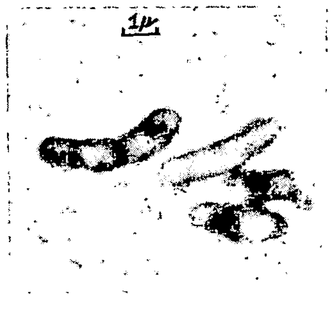

Fig. 2. Isolated cockroach mitochondria. Shorter incubation. Shows deposits as dots and straight and curved transverse bars. (× 4,000)

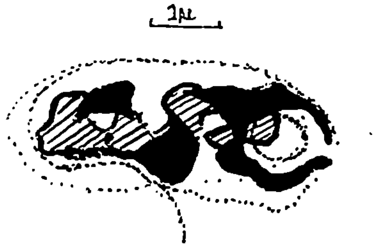

Fig. 4. Composite tracing of deposition of cobalt-formazan at various levels within a single mitochondrion. Shows the spiral form referred to in the text. × 8,000

the body of a single mitochondrion, by superimposing the photographic images obtained at different depths of focus. The tracing clearly shows that the structure revealed by the metal-formazan deposits exists in the form of a helix, and we suggest, therefore, that the cristæ mitochondriales may occur not as complete or incomplete transverse bars but as a single continuous spiral.

The presence of a similar arrangement of mitochondria in the axial filament of mammalian spermatozoa and of the sites of succinic dehydrogenase activity in *B. subtilis* suggests, furthermore, that the helix may represent a pattern of enzyme localization common to many biological forms.

Electrical Responses of Frog Spinal Ganglion Cells in Sodium-free Media

Since Lorente de Nó[1] found that a group of small axons ("Et fibres") in the frog are able to conduct prolonged action potentials when the external sodium is replaced by certain quaternary ammonium ions, special attention has been directed to the effects of these compounds on other excitable tissues. Fatt and Katz[2] observed that the electrical responses of crustacean muscle fibres are maintained and even intensified when choline, tetramethylammonium, tetraethylammonium or tetrabutylammonium ions are substituted for the sodium in the external medium. No other excitable tissue, however, has been reported to show active responses after complete replacement of sodium by these ions. Choline, in particular, has repeatedly been used as an 'inert' osmotic substitute in experiments on sodium depletion in the extracellular spaces. At low concentrations, for example, 10–20 per cent replacement of sodium, tetraethylammonium lengthens the falling phase of the action potential of crustacean nerve[3] and of frog twitch muscle[4]. The intracellular injection of tetraethylammonium into the giant axon of the squid prolongs the duration of the action potential[5]. In frog nerve fibres, the enhancement of the negative after-potential produced by addition of tetraethylammonium to the Ringer's solution is more prominent in the terminal endings than in the nodes[6], suggesting that quaternary ammonium ions might act in different degrees on the various parts of the neurone.

Cell-bodies in the spinal ganglion of the frog have characteristic properties as compared with the axonal node[7], and it was therefore expected that specific effects of quaternary ammonium compounds could be revealed on the cell membrane. In the course of the investigation with these ions, it was found that the electrical activity of the ganglion cells could be maintained when the sodium of the Ringer's solution was totally replaced by choline or tetraethylammonium. The ninth or tenth lumbar spinal ganglion was isolated from *Rana pipiens*, together with the sciatic plexus branch and the dorsal root. The capsule covering the ganglion and the connective tissue adhering to the cells were carefully removed. The individual nerve cell-bodies (about 60μ diam.) could then be clearly seen so that the insertion of a microelectrode could be carried out under visual control. By use of the arrangement previously described[8], the superficial cells were directly stimulated with short pulses and the action potentials recorded through a single intracellular microelectrode.

When the preparation was soaked in a sodium-free sucrose–Ringer's solution for 3 hr., there was no appreciable effect on the resting potential of the cells, and no spike potential could be detected. Occasionally, a graded abortive response to very large stimuli was still observed in a few cells. After 3–5 hr. in sodium-free choline–Ringer's solution, the resting potential had a normal value (about 65 mV.) immediately after insertion of the micro-electrode, but tended to fall with time. No action potential could be indirectly evoked in the cell-bodies by stimulation of either root or nerve fibres. If direct stimulation was delivered through the microelectrode, however, large responses were regularly produced in the cell-body membrane. In Fig. 1, records 2 and 3 represent action potentials recorded in choline–Ringer's solution, while records 1 and 4 represent control responses obtained in normal Ringer's solution before and after the choline treatment respectively. The threshold for initiation of 'choline potentials' was higher than for 'sodium potentials', while the rate of rise of the spikes was diminished and their falling phase enormously prolonged. The entire configuration of the action potential was somewhat similar to that of crustacean muscle fibres in choline[2]. The excitability of the nerve cell-bodies was maintained even after several hours in choline, and the effect of the latter was perfectly reversible by re-immersing in Ringer's solution. In other experiments, the occurrence of

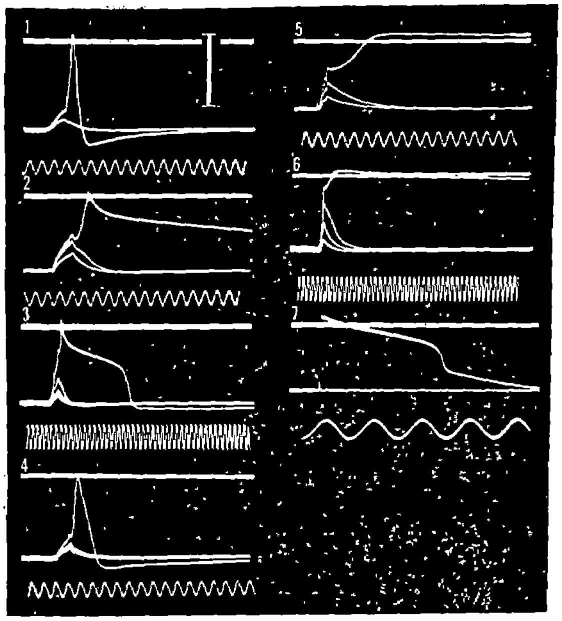

Fig. 1. Records 1–4 were obtained from the same preparation. Records 2 and 3 are 'choline potentials' recorded at different sweep speeds, and records 1 and 4 are 'sodium potentials' recorded before and immediately after soaking in choline Ringer's solution. Records 5–7 show 'tetraethylammonium potentials' at different sweep speeds obtained from another preparation. Time marks: 1 msec., except for Record 7 (100 msec.). Calibration: 50 mV.

'choline potentials' was confirmed in preparations previously blocked after several hours in sucrose Ringer's solution. The action of tetraethylammonium was even more striking than that of choline; action potentials were tremendously prolonged, their duration reaching usually ½–1 sec. Records 5–7 show typical 'tetraethylammonium potentials' recorded at different sweep speeds.

These results demonstrate that choline and tetraethylammonium ions are not 'inert' on the neurone cell-body of the spinal ganglion, but have a specific action which apparently reinforces the membrane excitatory processes. In discussing the nature of action potentials observed in media where the sodium has been completely replaced by choline or tetraethylammonium, it might be argued that some residual sodium exists in the intersticial spaces immediately surrounding the cell-bodies or accumulates as a result of slow leakage from the cell interior. This possibility cannot easily be disproved, but the conservation of cell excitability even after 8 hr. soaking in choline, and its rapid recovery in the latter after a prolonged immersion in sucrose–Ringer's solution apparently argue against an appreciable retention. Indeed, the concentration of extracellular sodium is probably less than the intracellular, particularly in the case of the superficial cells. If ionic currents underly the electrical activity observed in these experiments, there are three conceivable ways of accounting for the mechanism of the 'choline' or 'tetraethylammonium potentials': (1) by an influx of residual extracellular sodium (along a low or even reversed concentration gradient) or of some other cation (for example, calcium) through the active membrane; (2) by an outflux of an internal anion; or (3) by an inward transfer of charges transported by choline or tetraethylammonium ions. The first explanation would imply that, in the cell-body, choline and tetraethylammonium somehow facilitate the normal excitatory process. There is no evidence, as yet, that choline or tetraethylammonium ions penetrate the nerve cell during its electrical activity.

A Histological Stain for Newly Calcified Tissues

During investigations in which sudan black *B* was used for studying the lipoid inclusions in cells of bone and teeth[1], it was found that dentin, enamel, cartilage and bone did not stain significantly unless they were previously extracted with pyridine at 60° C., when characteristic staining reactions were obtained.

Rats' upper incisor teeth with the surrounding tissue and the proximal ends of tibias were used. After fixation and treatment with pyridine, and decalcification in some instances, they were embedded in gelatin and cut frozen. The sections were stained with sudan black *B* (George T. Gurr), using Baker's method[2] and mounted in glycerine jelly. Unextracted sections were also stained with toluidine blue and examined mounted in water, only undecalcified tissues being used. The perchloric acid technique for the removal of ribonucleic and deoxyribonucleic acids and the periodic acid–Schiff method were also employed. Some sections were treated with hyaluronidase for 24 hr. at 37° C. at *p*H 5·7.

When they were stained with sudan black without preliminary treatment with pyridine, the hard tissues were a uniform pale blue colour. After treatment with pyridine all areas where calcification was being initiated stained deep blue or black. These areas were at the predentin–dentin junction (Fig. 1), the

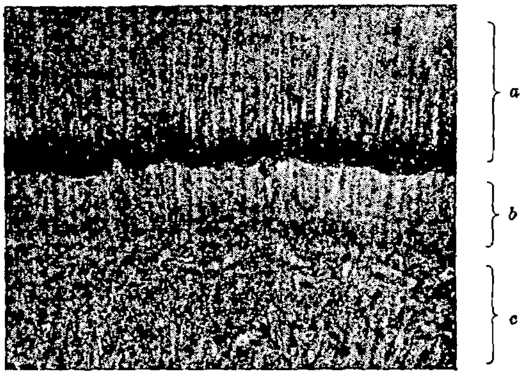

Fig. 1. Transverse section of labial side of formative end of undecalcified rat incisor tooth. (*a*) Dentin, (*b*) predentin, (*c*) odontoblasts and pulp. Note darkly stained line at dentin–predentin junction. Stained with sudan black *B* after treatment with hot pyridine, as described in the text. × 430

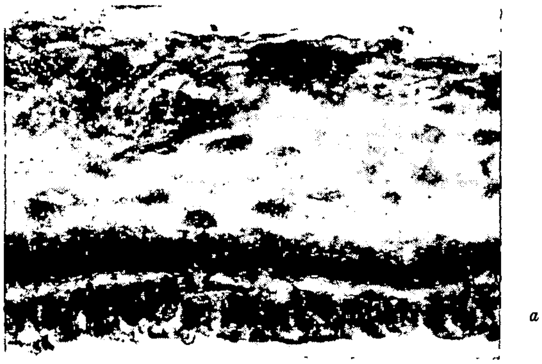

Fig. 2. Part of maxillary alveolar bone of rat. At the top an osteoclast can be seen and below a row of osteoblasts (*a*). Note intense staining line on appositional side of bone, separated from the osteoblasts by a narrow rim of matrix. Stained with sudan black *B* after treatment with hot pyridine, as described in the text. × 430

part of the organic enamel where it became acid-soluble, a line on the appositional side of bone, but a short distance inwards (Fig. 2), and the intercellular matrix between the hypertrophic cells of the epiphyseal cartilage just before their removal (Fig. 3). These areas in the incisor were also metachromatic, but bone and epiphyseal cartilage could only be examined after decalcification, when the whole tissue was metachromatic. Treatment with pepsin did not affect the staining of the teeth. Hyaluronidase did not abolish either the metachromasia of the teeth or the sudan black staining of any of the tissues. Treatment with perchloric acid did not change the staining reactions. No specific staining of the dentin–predentin junction was observed with the periodic acid–Schiff technique.

For sudan black to stain in these ways, treatment with pyridine had to precede decalcification, though decalcification was not necessary. Treatment with hot formalin solution instead of pyridine did not cause the characteristic sudan black staining. Extraction with pyridine made no difference to the metachromatic staining.

It seems probable that under the conditions of these experiments, sudan black is staining some fraction of the mucopolysaccharides, but is a good deal more selective in this respect than toluidine blue. The process underlying pyridine treatment seems from the work of Hadadian and Pirrie[3] to be some sort of precipitation. This makes the material insoluble in acid and stainable with sudan black.

Fig. 3. Longitudinal section of part of tibial epiphyseal cartilage of young rat, showing large hypertrophic cells and, below, the zone of cell erosion. Note the staining of the intercellular matrix between the hypertrophic cells. Stained with sudan black *B* after treatment with hot pyridine, as described in the text. × 430

Leblond *et al.*[4] have found the dentin–predentin junction to be strongly metachromatic, and Bélanger[5] reported that sulphur-35 is laid down here two hours after injection. The puzzling aspect is that both sudan black and toluidine blue stain this area only, although the zone of sulphur-35, as seen by autoradiographs, moved progressively outwards with accretion of more dentin[5]. What is the difference between the mucopolysaccharide at the dentin–predentin junction and that in the depths of the dentin ? Scott and Pease[6], in electron microscope studies, have noted that a fibrous preosseous matrix exists between the osteoblasts and calcified bone matrix, and the width of this zone is about the same as that in the present findings. But, as with dentin, only the first narrow strip of calcified bone stained with sudan black.

Although it was not possible to compare the staining with sudan black and toluidine blue in bone, I consider that the similarity of the two appearances in teeth is sufficient to conclude that the same constituent of the tissue is being stained.

Rubidium-86 as a Tracer of Potassium in Man

Serial estimations of exchangeable potassium cannot be made after a single dose of potassium-42 because the half-life of the isotope (12·4 hr.) is too short. Rubidium-86 (half-life, 19·5 days) and potassium appear to be handled similarly in man, and Burch *et al.*[1] have suggested that this isotope could be used as a potassium tracer in prolonged studies.

We have compared changes in potassium-balance in three subjects measured by a metabolic-balance technique (in which intake and output by all routes are estimated by chemical methods) with changes in exchangeable 'potassium' measured by the cumulative excretion isotope dilution method after a single dose of 100 μc. of rubidium-86 by mouth. 5–8 days were allowed for equilibration and samples of lysed red cells and of 24-hr. and 'spot' collections of urine were counted in a Geiger–Müller dip-counter and in a scintillation counter. The double counting was necessary because sodium-22 was given simultaneously[2]. Errors of counting and of flame photometry were estimated to be 3·8 per cent.

We found that the specific activities of red cells and particularly of urine fluctuated unpredictably

Table 1

Subject	Duration of study (days)	Changes in balance during study (m.equiv.)		
		Chemical method	Rubidium-86 method, specific activities calculated from : 'Spot' urine	Red cells
Premenstrual fluid retention	9	− 30	+ 10	+ 5
Steroid withdrawal after adrenalectomy	7	+ 70	+400	+140
Removal of adrenal adenoma causing Cushing's syndrome	16	+150	−120	+340

from day to day, and calculations of exchangeable 'potassium' were therefore made from figures obtained from idealized graphs of observed values. The specific activity of urine was always less than that of red cells collected at the same time. In one patient, after nine days equilibration, there was close agreement between the specific activities of red cells and muscle (each 1,740 counts/min./m.equiv. potassium) and adrenal tissue (1,750 counts/min./m.equiv. potassium), while fasting urine collected at the same time had a specific activity of 1,220 counts/min./m.equiv. potassium. The overall results for the three patients are shown in Table 1 and the day-to-day results for one of them are shown in Fig. 1.

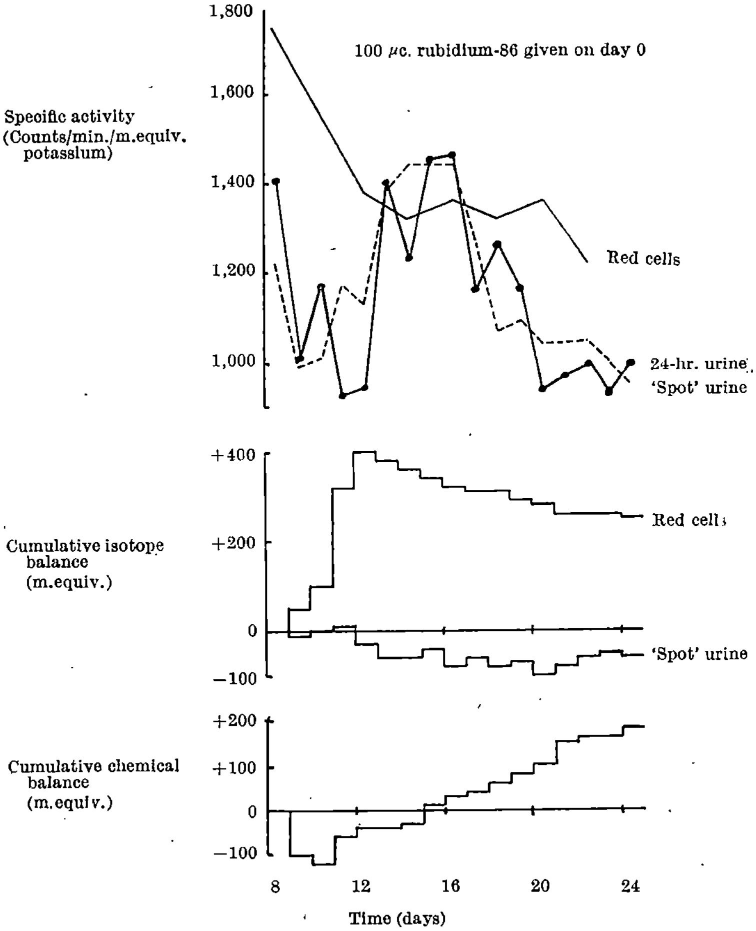

Fig. 1. Woman aged 35. Removal of adrenal adenoma on day 9

We feel that the magnitude of the errors and the variations of specific activity make rubidium-86 unsuitable as a potassium tracer, certainly for prolonged studies. We thank Prof. J. E. Roberts, Dr. J. D. N. Nabarro and Dr. K. Jones for their advice. The work was done during the tenure of a Leverhulme Research Scholarship by one of us (M. M. M.).

Lymphotrophic Antibiotics

MOST antibiotics are crystalloid molecules and are, for this reason, primarily circulated through the body by a vascular route. Concentrations of antibiotics in lymph and lymph nodes are often difficult to raise to significant levels. On the other hand, it is an established fact that macromolecules and colloidal particles have a particular affinity for the lymphatic system and can therefore attain high concentrations in lymph and lymph nodes.

We have combined streptomycin, neomycin, viomycin and streptothrycin with carboxyl, sulphonic or phosphorylated high molecular compounds and studied the changes in their pharmacological properties.

In one series of experiments the question of the colloidal versus the crystalloid behaviour of these preparations was examined. To this end these substances were infused into a peripheral lymph vessel of the hind extremity of a dog at a constant rate and the amount appearing in the thoracic drainage was measured over a period of 4 hr. The results were compared with the perfusion with a colloidal (dextran) and a crystalloid substance (*para*-aminohippuric acid).

Further experiments were performed in dogs in which blood- and lymph-levels (thoracic duct cannulation) were measured after intramuscular, intraperitoneal, intrapleural, etc., administration. In another series of experiments these substances were injected intramuscularly, intrapleurally, etc., and concentrations were followed in local lymph nodes. We further investigated the blood-levels of these new substances after various means of application as compared with streptomycin and neomycin.

Finally, we have investigated changes in the acute toxicity of these substances in macromolecular combinations.

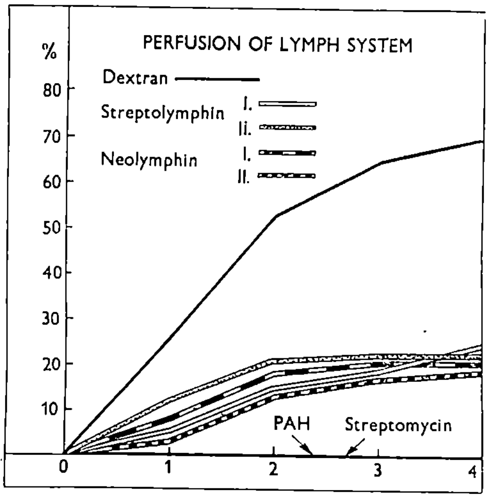

Fig. 1. The percentage of substance in the thoracic lymph drainage infused into the peripheral lymph vessel, with: dextran, neolymphin I, neolymphin II, streptolymphin II, *para*-aminohippuric acid, streptomycin, neomycin, penicillin (basic zero-line)

These macromolecular salts, which have been termed 'antibiolymphins', fall under three headings: (1) salts of antibiotic bases with polyacrylic acids (streptolymphin I, neolymphin I); (2) salts of antibiotic bases with sulphonic or phosphorylated polysaccharides (streptolymphin II, neolymphin II); (3) salts of antibiotic bases with natural polycarboxyl acids from a series of polyuronic substances and polysaccharide derivatives containing carboxyl groups (streptolymphin III, neolymphin III).

Antibiolymphins have the following pharmacological properties:

(1) Their physiological behaviour comes somewhere between a pure crystalloid and a pure colloid. This is shown in Fig. 1, which shows the percentage of substance appearing in the thoracic drainage with dextran infusion and *para*-aminohippuric acid. In 4 hr., 70 per cent of dextran appeared in the thoracic lymph drainage, whereas the *para*-aminohippuric concentration in lymph was insignificant. Streptomycin, neomycin and penicillin acted like *para*-aminohippuric acid. Streptolymphin and neolymphin acted more like a pure colloid, since in 4 hr. 20 per cent collected in the thoracic duct.

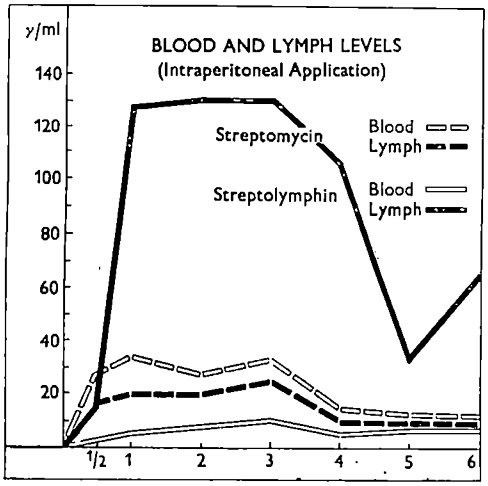

Fig. 2. Blood- and lymph-levels of streptomycin and streptolymphin (thoracic duct cannulation) after intraperitoneal application

(2) Antibiolymphins, as compared with the generally used antibiotic preparations, are absorbed from the injection locus primarily by the lymphatic system. Fig. 2 shows the rate of absorption of streptomycin and streptolymphin I from the peritoneal cavity in a dog. It can be seen that streptomycin concentration is high in blood, low in lymph, while the reverse obtains with streptolymphin I.

(3) A high concentration of long duration may be produced in the lymph nodes of the drainage channels. Fig. 3 shows the tissue concentration of streptomycin and streptolymphin I in the para-aortal lymph nodes after intramuscular application into the hind extremity of a dog at various intervals after the application. It is seen that streptomycin is producing relatively low concentrations and disappears rapidly (after the fourth hour). The streptolymphin-levels are far higher and the time of their disappearance is 72 hr. and more. Similar results have been obtained with sternal and mediastinal nodes after intrapleural application.

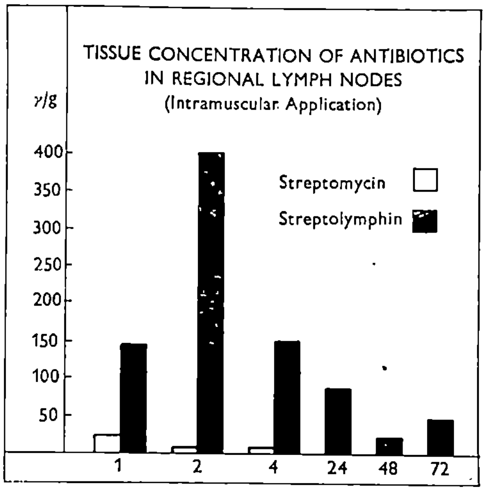

Fig. 3. Tissue concentrations of streptomycin and streptolymphin I in the para-aortal lymph nodes after intramuscular application into the hind extremity of dogs

(4) In comparison with the normal antibiotic equivalent, the blood-level is lower but maintained for a longer time, since the absorption of macromolecules via the lymph system is a slow process. Thus, neomycin disappears from the pleural cavity after 4 hr., while neolymphin was still present after 48–72 hr. and more.

(5) The acute toxicity is much less. For example, the *LD*50 in rats and mice is raised five times with streptolymphin I and ten times with neolymphin I.

In conclusion, we believe that the same chemical principle of tissue localization can be applied with other substances as well, be they antibiotic, cytostatic, chemotherapeutic, etc.

Experimental Suppression of the Early Inflammatory Phenomena of Turpentine Pleurisy in Rats

Previous work[1–3] has indicated that the increased capillary permeability and resultant exudate that follows intrapleural injection of turpentine in rats might be due at first to local release of histamine or 5-hydroxytryptamine, or both, and later to activation of other mechanisms.

In order to obtain experimental support for this hypothesis it was decided, by employing measures solely designed to block the specific action of histamine and 5-hydroxytryptamine, to attempt to suppress the formation of the very early exudates, leaving the later exudates unchanged.

Repeated injections of the histamine liberator 48/80 deplete many body tissues of histamine and 5-hydroxytryptamine and prevent certain reactions dependent on release of these substances[4–6]. In the present work 150-gm. albino rats were given 100 µgm. intraperitoneally of 48/80 twice daily for seven doses, then two further doses of 200 µgm. 5 hr. after the last injection, 0·1 ml. of turpentine was injected into the right pleural cavity and the animals killed 30 min. later. As can be seen from Table 1, prior depletion of the rats with 48/80 led to virtually total suppression of the 30-min. pleural exudate. When the interval between injection of turpentine and killing the animal was prolonged to 1–2 hr., the volume of pleural exudate obtained from rats depleted of histamine and 5-hydroxytryptamine with 48/80 increased. However, even at 2 hr. the amount of exudate was less than half of that withdrawn from non-depleted controls. When the interval between injections of turpentine and death was prolonged to 4 hr., however, no significant difference in the volume of exudates was observed between depleted and control groups.

A further injection of 200 µgm. of 48/80 at the time the rats received their intrapleural turpentine failed to decrease the volume of the 4-hr. exudate.

When, instead of a course of such injections, rats were given a single dose of 200 µgm. of 48/80 4½ hr. before injection of turpentine, and killed 30 min. later, the volume of pleural exudate obtained did not differ significantly from that obtained from control animals.

These experiments were repeated using the histamine liberator 'Polymixin *B*' instead of 48/80 [7]. Rats were given 0·5 mgm. 'Polymixin' intraperitoneally twice daily for nine doses and the experiment commenced 5 hr. after the last injection. As can be seen from Table 1, the results were essentially similar to those obtained with 48/80 except that suppression of the volume of the 30-min. exudate was not as complete.

Table 1

Time after intrapleural turpentine	Group	No. of animals	Mean vol. of exudate (ml.)	Standard deviation	*P*
30 min.	Controls	18	0·96	±0·07	
30 min.	48/80	18	0·1	±0·07	< 0·001
30 min.	'Polymixin'	10	0·26	±0·11	< 0·001
30 min.	Anthisan	8	0·1	±0·05	< 0·001
2 hr.	Controls	11	1·35	±0·39	
2 hr.	Anthisan	8	0·86	±0·3	< 0·02
2 hr.	48/80	6	0·43	±0·18	< 0·001
4 hr.	Controls	11	1·5	±0·74	
4 hr.	48/80	15	1·2	±0·25	< 0·8 (N.S.)
4 hr.	Anthisan	7	1·6	±0·6	< 0·8 (N.S.)

To confirm the role of histamine suggested by these depletion experiments 'Mepyramine' maleate[8] was injected intravenously in a dosage of 1 mgm./kgm. and turpentine injected intrapleurally 10 min. later. As can be seen from Table 1, the results were similar to those of the depletion experiments. In order to determine whether the appearance of an unaltered volume of exudate at 4 hr. was due to the effect of the drug wearing off, a group of rats was given two further intravenous injections of the same dose of 'Mepyramine' maleate at 45-min. intervals in the 4-hr. period between injection of turpentine and death of the animal. However, these rats showed no reduction in the volume of their pleural exudates, which again did not differ significantly from those of 4-hr. exudates in control animals. To confirm that the action was shared by another antihistamine, promethazine hydrochloric acid ('Phenergan'), 1 mgm./kgm., was substituted for 'Mepyramine'. Once again practically total suppression of 30-min. exudates was obtained, the 4-hr. exudates not differing significantly in volume from the controls.

Previous experiments[2,3] had suggested that 5-hydroxytryptamine might play a part as chemical mediator in the early stages of turpentine pleurisy. Reserpine, a *Rauwolfia* alkaloid, depletes much of the 5-hydroxytryptamine in tissues[7,9]. The substance was injected intraperitoneally into eight 150-gm. rats, four doses of 1·0 mgm. being given over 3 days. 18 hr. after the last injection, 0·1 ml. of turpentine was given intrapleurally and the animals killed 30 min. later. Six rats had pleural exudates the volume of which ranged between 0·8 and 1·1 ml., that is, within the range observed in control animals. The remaining two rats had only 0·1–0·2 ml. of exudate; but both these animals were in a state of profound collapse and unconsciousness and showed no reaction even when the pleural cavity was opened. That extreme hypotension existed in these animals could be shown by the almost non-existent blood flow on cutting the carotid artery. Under these conditions it seems likely that the blood pressure was too low for effective filtration to occur through the permeable pleural capillaries. The failure of reserpine to alter the initial response of the pleura to turpentine was confirmed by the use of '*BOL* 148' (2-brom-D-lysergic acid diethylamide bitartrate). This substance is a powerful inhibitor of 5-hydroxytryptamine[10]. 0·5 mgm. was given intravenously to 150-gm. rats and 10 min., and in some instances 30 min., later 0·1 ml. turpentine was injected into the right pleural cavity, the animals being killed 30 min. afterwards. No significant difference was observed in the volume of pleural exudates of these and of control rats also killed 30 min after intrapleural turpentine.

That the effect of 48/80 and 'Mepyramine' was not due to a general depression of capillary permeability was shown by skin tests on rats injected intravenously with trypan blue.

A greatly increased rate of removal of fluid and protein from the pleural cavity might in theory account for the great diminution in 30-min. exudates. That this is not in fact the case was shown by injecting 1 ml. of rat serum into the pleural cavity of control rats depleted with 48/80 and rats pre-treated with 'Mepyramine'. The serum was absorbed at a similar slow rate in all three groups.

The present results appear to provide strong support for the hypothesis that the initial inflammatory phenomena of turpentine pleurisy in the rat are largely due to local release of histamine and that other factors then come into play to prolong the increased capillary permeability thus initiated, the two systems apparently working quite independently. That 5-hydroxytryptamine may play a subsidiary part in the 'histamine phase' is possibly suggested by the diminished effectiveness of 'Polymixin' relative to 48/80 and by more rapid accumulation of exudate seen in 'Mepyramine'-treated rats compared with rats depleted of histamine and 5-hydroxytryptamine by 48/80. Further work is in progress, and the results will be discussed more fully elsewhere.

We thank Sir Roy Cameron for guidance and encouragement, Dr. R. Moulton for helpful discussion and Messrs. Sandoz for supplying '*BOL* 148', and Messrs. Burroughs Wellcome for supplying compound 48/80.

Vanillic Acid Excretion during Stress

Recent reports of the metabolic conversion of the 3 : 4-dihydroxyphenyl into the 4-hydroxy-3-methoxyphenyl grouping[1,2] and of the occurrence in urine of 4-hydroxy-3-methoxymandelic acid[3], a metabolite of adrenaline and noradrenaline, prompt us to record briefly our own findings along these lines. Aromatic compounds extracted by ether from acid-hydrolysed urine have been examined chromatographically by a method[4] derived from that described by Boscott[5]; methylated products have been found to be invariably excreted by human subjects following oral administration of small doses (100–300 mgm.) of catechols. The compounds fed and metabolites detected are so similar to those described previously as to need little further comment ; however, it has been observed, in one case at least, that methylation is not necessarily confined to the hydroxyl group in the 3-position, since 3-hydroxy-4-methoxycinnamic acid has been identified, together with the isomeric 4-hydroxy-3-methoxy compound, among the substances detected following administration of caffeic (3,4-dihydroxycinnamic) acid. Both these acids have been regularly detected in normal urines following acid hydrolysis.

These experiments were stimulated by the observation that some subjects exposed to prolonged periods of stress were found to excrete abnormally large amounts of a substance apparently chromatographically identical with 4-hydroxy-3-methoxybenzoic (vanillic) acid. Ten urine samples were successfully collected over 5–10 hr. periods late in the first or second day from subjects participating in a motor-car rally necessitating continuous vigilance and lack of sleep for 48 hr. One subject excreted large amounts of the acid on both days, two subjects on the first day only and one on the second day only. Two further subjects, who each gave only one urine sample, excreted only normal amounts. Many subjects failed to produce an adequate quantity of urine owing to restricted fluid intake ; some of the subjects had received large doses of nicotinamide in connexion with other investigations, but this did not appear to influence vanillic acid excretion. Although no proper dietary control was possible, it did not appear that anything unusual had been eaten by the subjects ; however, they may well have tended to eat similar meals which fortuitously may have contained vanillic acid or some precursor.

However, it is certainly tempting to postulate that excretion of vanillic acid reflects secretion of adrenaline and noradrenaline in stress situations. It would not appear profitable at this stage to contrast the finding of vanillic acid in hydrolysed urines with that of 4-hydroxy-3-methoxymandelic acid in unhydrolysed urine[3], and it is hoped that future opportunities may occur to enable us to clarify the situation. The experiments described form part of an investigation into the possibility that metabolites of adrenaline may be responsible for the mental effects of prolonged stress ; as an alternative approach to this problem, the synthesis and metabolism of compounds intermediate in structure between adrenaline and mescaline are also being studied.

We wish to thank the Director-General of Medical Services, Royal Air Force, for permission to publish this work.

Relative Distribution and Chemical Nature of the Fuel Store of the Two Types of Fibres in the Pectoralis Major Muscle of the Pigeon

George and Jyoti[1] showed that the pectoralis major muscle of the pigeon consists of two types of fibres : a broad variety, well striated and with clear sarcoplasm, having very few inclusions, and the other a narrow type, with dense lipoid inclusions and striations scarcely visible. They also observed that the fat globules in the narrow fibres become fewer after strenuous muscular exercise and suggested the possibility of the utilization of fat in such muscular activity. In the present work, we have investigated the relative distribution of the two types of fibres in the muscle and the chemical nature of the fuel store in them.

Pieces of muscle from a pigeon immediately after it was decapitated and fixed in formalin – calcium chloride fixative[2] (1 gm. of calcium chloride dissolved in 100 c.c. of 10 per cent formalin) were sectioned with a freezing microtome and stained with sudan black *B*

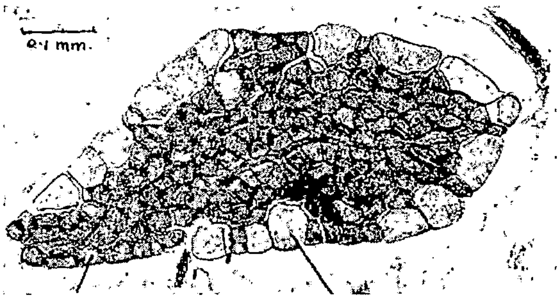

Fig. 1. Photomicrograph of a transverse section of a fasciculus in the pectoralis major muscle of the pigeon, stained with sudan black *B*

(Fig. 1). The narrow fibres were deeply stained whereas the broad ones were completely unstained, thereby showing that the former are fat-loaded fibres.

Pieces of the muscle were taken from a pigeon immediately after it was decapitated, and some were fixed in picric acid-saturated alcohol–formalin and the rest preserved in 80 per cent methanol, ice-cold fixative being used in both cases. Microtome sections of the fixed muscle were cut at 8μ and stained with Best carmine stain (after Bensley[3]) for glycogen and lightly counterstained with hæmatoxylin. The narrow fibres were faintly stained, whereas the broad ones, the majority of which are confined to the periphery of the fasciculus (Figs. 1 and 2), were stained a brilliant red (Fig. 2), denoting a comparatively high percentage of glycogen in them. A control slide, which was incubated in diastase solution in order to digest and remove the glycogen prior to staining, did not show the characteristic red colour for glycogen.

From the pieces of the muscle preserved in methanol, the broad and the narrow fibres were separately isolated in sufficient quantities to yield at least 2–3 mgm. of the material in dry weight, by carefully teasing them out by means of very fine forceps under a stereoscopic dissection microscope. The broad and narrow fibres thus collected in separate containers were dried in a desiccator under vacuum and weighed on a microbalance. The glycogen content of the two types of fibres was estimated on the dry weight of the fibres preserved in methanol. The method employed in the estimation of glycogen was a colorimetric micro-method (after Kemp *et al.*[4]) using the Beckman spectrophotometer (*DU* model). Since the fibres were preserved in methanol, which, being a fat solvent, would have dissolved some fat during preservation and, since the relative fat content of the two types of fibres differs considerably, the calculation of the glycogen content based on dry weight of the material thus preserved would not give accurate figures for glycogen. Therefore it was thought more desirable to express the relative glycogen content of the two types of fibres (per unit dry weight of the material preserved in 80 per cent methanol) as a ratio rather than in actual percentage figures.

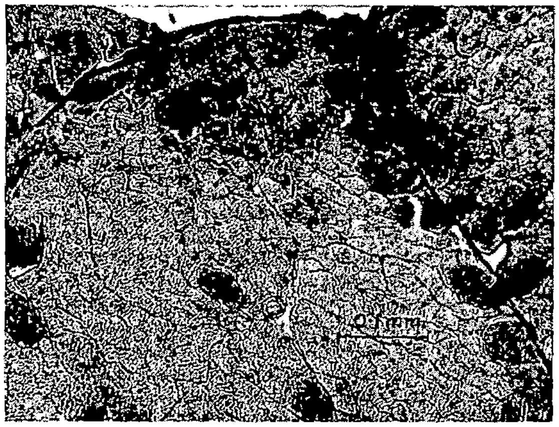

Fig. 2. Photomicrograph of a transverse section of a piece of pectoralis major muscle of the pigeon, stained with Best carmine

The diameter of the fibres in a fasciculus was measured from the section of a frozen piece of fresh muscle. The measurement was made indirectly from a camera lucida sketch using a micrometer slide. The ratio of broad to narrow fibres more or less in the middle of the muscle was found to be 1 : 16. The number of the narrow ones to one broad was found to vary in the different regions of the muscle.

Table 1

	Narrow fibres	Broad fibres
1 Appearance of fresh fibres	1 Highly granulated with fat globules and granules obscuring the striations 2 Red in colour	1 Practically devoid of fat globules and granules. Striations clear 2. White, translucent
2 Distribution within a fasciculus	Mostly in the interior	Mostly on the periphery
3 Relative number within a fasciculus	16 : 1	
4 Relative diameter of fibres in cross-section of fresh frozen muscle	1 : 2	
5 Relative glycogen content per unit dry weight of material preserved in 80 per cent methanol	1 : 5	
6 Nature of the fibres (fuel store)	Fat-loaded	Glycogen-loaded

The present work has shown that the narrow fibres are fat-loaded and that the broad ones are glycogen-loaded, having about five times the glycogen store of the other type. George and Jyoti[5] have shown that a considerable amount of fat is reduced in the breast muscle of the bird and bat during exercise and that fat is the chief fuel during sustained muscular activity (George, J. C., and Jyoti, D., unpublished work). Very recently, George and Scaria[6] have demonstrated a large amount of lipase in the breast muscle of the pigeon, obviously for the conversion of fat into fatty acids and glycerol, which is the first step in the utilization of fat for energy.

In the light of these findings, the presence of the two types of muscle fibres, the glycogen-loaded, broad ones and fat-loaded, narrow ones, in the most powerful flight muscle of the pigeon, is of special interest. Obviously the fat-loaded, narrow fibres which predominate are adapted for sustained flight, and the few, broad, glycogen-loaded ones for quick and sudden action. On the other hand, in some birds, for example, the parakeet (*Psittacula krameri*) and the bee-eater (*Merops orientalis*), the pectoralis major muscle consists of only the narrow variety of fibres, the broad ones being absent altogether, while there are others, for example, the domestic fowl

(*Gallus domesticus*) and the kite (*Milvus migrans*), in which there is only the broad variety[7]. Hence an understanding of the exact role of the two types of fibres in the pectoralis major muscle of the pigeon requires a detailed study of the fibrillar structure and its evolution in different birds, and also in relation with other body muscles, particularly those concerned with flight. This is now being undertaken.

Effect of Human α_1-Acid Glycoprotein on Blood Coagulation

As yet no specific function of the α_1-glycoproteins has been demonstrated. The average amount of α_1-acid glycoprotein in normal plasma is 50 mgm. per 100 ml. The alpha-glycoproteins have been found to be increased in many pathological conditions, including cancer and diseases associated with tissue destruction such as in the inflammatory dermatoses.

On addition of α_1-acid glycoprotein to normal plasma we noticed a prolongation of the time of coagulation, which prompted further investigation of such effects.

Most of the methods employed have already been described. α_1-Acid glycoprotein was prepared from human plasma in the manner described by Yamashina[2]. Unless otherwise stated, 1 per cent solution of α_1-acid glycoprotein in imidazole buffer of *p*H 7·25 and ionic strength 0·15 was used for the clotting tests. The solution showed no thrombin, prothrombin, proconvertin or proaccelerin activity; it did not delay the clotting of fibrinogen by thrombin; in tests on plasma, it showed no immediate or progressive anti-thrombin activity; tested on fibrin plates it did not show any plasmin or plasminogen-activator activity; it had no plasmin inhibitory effect, but it did inhibit the transformation of plasminogen to plasmin by urokinase (P. Wallén and I. Yamashina, unpublished work).

The effect of α_1-acid glycoprotein on the activation of bovine prothrombin prepared according to the method of Seegers[3] in 25 per cent sodium citrate solution was also studied. Addition of 20 mgm. of α_1-acid glycoprotein to 9 mgm. of prothrombin did not demonstrably inhibit the prothrombin activation.

In the investigation of the mechanism of anticoagulant action of acid glycoprotein, we used the test system of Owren and Aas[4] for the determination of prothrombin and proconvertin. (Clotting mixture: 0·2 ml. of barium sulphate-adsorbed bovine oxalated plasma + 0·2 ml. of human brain thromboplastin + 0·2 ml. of α_1-acid glycoprotein solution (or buffer) + 0·2 ml. of normal citrated plasma in varying concentrations + 0·2 ml. of 0·03 *M* calcium chloride solution). The variables in this test system were prothrombin and proconvertin (citrated plasma), thromboplastin, proaccelerin (barium sulphate-adsorbed bovine plasma), calcium and α_1-acid glycoprotein. The latter was found to inhibit coagulation. For example, when the clotting mixture consisted of undiluted thromboplastin, diluted citrated plasma (1/10) and an excess of proaccelerin and calcium, acid glycoprotein in a final concentration of 2·5 mgm. per ml. prolonged the clotting time from 33 to 83 sec. and 0·5 mgm. per ml. to 43 sec. It is clear from Fig. 1 that in the presence of a constant amount of thromboplastin and excess of proaccelerin and calcium, α_1-acid glycoprotein inhibited the transformation of prothrombin to thrombin in a competitive manner. With 1/1 to 1/1,000 dilutions of thromboplastin the factor by which the slope of the line increased was invariable. Decreasing concentrations of proaccelerin in the test system did not increase the anti-coagulant effect of acid glycoprotein, neither did variations in the amount of calcium.

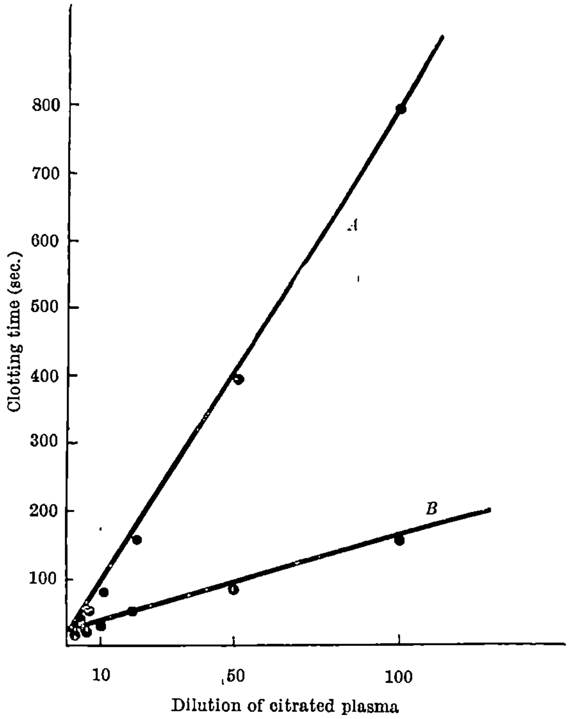

Fig. 1. The inhibition of α_1-acid glycoprotein in the one-stage prothrombin test system (expressed according to Lineweaver and Burk). *A*, acid glycoprotein (2·5 mgm./ml.); *B*, no acid glycoprotein

It was also demonstrated by the thromboplastin-generation test that acid glycoprotein inhibited the plasma thromboplastin in a manner similar to that for brain thromboplastin.

In view of these observations, the anticoagulant effect of acid glycoprotein could be attributed to an inhibition of the transformation of prothrombin to thrombin by thromboplastin in a competitive manner. Heating α_1-acid glycoprotein at 100° C. for 30 min. did not impair its anticoagulant effect, in agreement with the fact that boiling produces no change in its electrophoretic and ultracentrifugal patterns[5].

Corresponding experiments were carried out with albumin prepared according to Cohn's method 6 and reprecipitated. A 5 per cent solution of albumin in the same buffer as that used for the acid glycoprotein experiments showed no antithrombin effect. The albumin solution was, however, found to inhibit the citrate activation of prothrombin to thrombin. Thus, when 50 mgm. of albumin was added to 11 mgm. of prothrombin only 60 per cent of the prothrombin was activated. In the one-stage prothrombin test system used for acid glycoprotein described before, albumin in a final concentration of 12·5 mgm. per ml. prolonged the clotting time from 33 to 42 sec., instead of to 83 by 2·5 mgm. of acid glycoprotein per ml. The inhibition was interpreted as being noncompetitive.

The fact that acid glycoprotein has an antithromboplastic effect suggests the possibility that it plays a part in the coagulation of blood. Even the concentration of α_1-acid glycoprotein in normal plasma is sufficient to influence the clotting time. In diseases associated with a decrease of prothrombin or an increase of acid glycoprotein-levels, a more significant anticoagulant effect of acid glycoprotein can be expected because of the competitive inhibition for prothrombin activation by thromboplastin.

Interaction of Phenolic Compounds with Bacteria

THE interaction of several phenolic compounds with bacteria has been examined as part of an investigation of the mode of action of various antibacterial substances[1]. This communication summarizes the results obtained using hexylresorcinol and *Escherichia coli*.

Addition of hexylresorcinol to washed suspensions of *E. coli* (originally N.C.T.C. 5933) effected the release of substances which absorb in the ultra-violet (for convenience, these substances will be referred to as cell exudate) ($\lambda_{max.}$ 260 mμ) from the bacteria, reminiscent of the effects reported for various antibacterial surface-active agents[2]. Solutions containing hexylresorcinol and cell exudate were analysed spectrophotometrically after a quantitative separation involving a liquid–liquid extraction with an organic solvent. At low hexylresorcinol concentrations, the cell exudate released from the cell in 10 min. at 25° was proportional to the drug concentrations added. However, as the latter were increased, a limiting value was reached which corresponded to the bactericidal concentration of hexylresorcinol, defined in terms of the single mean survivor time of *E. coli* in an aqueous solution at 25°. Similar concentrations of the phenol greatly increased the light-scattering properties of suspensions of *E. coli* immediately upon contact between drug and bacteria.

The amount of hexylresorcinol taken up by the bacteria was proportional to the concentration of the drug to which they were exposed : no limiting value was reached, possibly due to the limited aqueous solubility of hexylresorcinol. At a bactericidal concentration of hexylresorcinol (single mean survivor time of 48 min.), the amount of drug bound per bacterium was greater than that required to form a close packed monomolecular layer surrounding the organism, whatever the orientation of the molecules with respect to the surface (assuming that the surface area of the cytoplasmic membrane approximates to the surface area of a cylinder, of maximum size 3μ × 0·8μ, in the living organism). The uptake of hexylresorcinol by isolated cell-wall preparations of *E. coli* was negligible. The observed changes in light-scattering properties of isolated cell walls and intact cells on addition of hexylresorcinol were not of comparable magnitude; the changes in light-scattering properties of the latter are attributed to the interaction of the drug with the cytoplasmic membrane.

The evidence available in the literature[3] suggests that the site of action of phenolic compounds is at the cytoplasmic membrane; the present results provide further evidence in favour of this hypothesis.

Phenolic compounds have little value as preservatives in preparations containing non-ionic surface-active agents[4]; the results obtained on addition of 'Cetomacrogol' to the hexylresorcinol–*E. coli* system provides evidence concerning the nature of this inactivation. Addition of 'Cetomacrogol', in as low a molecular ratio as possible without effecting insoluble complex formation, reduced the uptake of hexylresorcinol from solutions by *E. coli* at all concentration levels of the phenol studied. (Hexylresorcinol was determined colorimetrically in the presence of 'Cetomacrogol' due to difficulties associated with solvent extraction procedures in presence of surface-active agents.) The changes in light-scattering properties of suspensions of *E. coli* caused by the presence of hexylresorcinol were prevented by the addition of 'Cetomacrogol' to the drug solution. The antibacterial activity of hexylresorcinol (bactericidal and bacteriostatic activity) against *E. coli* was completely abolished in the presence of the non-ionic agent. However, sufficient hexylresorcinol was taken up by the bacteria from a solution containing the maximum attainable drug concentration and a low molar ratio of 'Cetomacrogol' to exert a bactericidal action in the absence of the surface-active agent. The 'Cetomacrogol' would therefore appear to prevent or interfere with the interaction of the drug with the cytoplasmic membrane.

A full account of experimental techniques and observations will be published elsewhere.

Filarial Infection in *Simulium griseicolle* Becker

In the course of a *Simulium* survey at Lokoja, Kabba Province, Northern Nigeria, in September 1956 adult *Simulium griseicolle* were found to be very abundant. Hitherto adults of this species had not been collected although it was known to breed along several hundred miles of the Niger River[1]. The flies were particularly numerous on the window-panes of the Lokoja catering rest-house, but they were also seen in villages some distance from Lokoja and one fly was collected 24 miles from the nearest breeding-site in the Niger.

In the Sudan *S. griseicolle* can be a troublesome man-biter[2,3]; but no evidence was found that the flies at Lokoja were biting man and sucking human blood although flies would frequently settle on the skin and crawl about for a short time, especially in the early morning (6.30–7.30 a.m.).

Although flies had not been seen to feed on man it was decided to dissect specimens and examine them for developing filariæ, for it had recently been found[4] that filarial infection occurred in *Simulium bovis* de Meillon, which although it occasionally feeds on man in Northern Nigeria[4] is not normally an anthropophilic species. Flies for dissection were collected on the window-panes in the Lokoja rest-house which lies about 1½ miles from the breeding-ground in the Niger.

It was surprising to find that some flies were infected with filarial worms, for so far as is known filarial infection in *S. griseicolle* has not previously been observed. The results are summarized in Table 1.

Table 1

Flies dissected	Flies with caudate 'sausage' forms	Flies with infective forms	Total flies infected
321	3 0·93 per cent	4 1·25 per cent	7 2·18 per cent

The caudate 'sausage' worms were embedded, as is usual with this stage, in the thoracic muscles, and the three flies harbouring caudate forms had one, two and three worms respectively. Of the four flies with infective forms the first had one worm only in the head, the second had one worm in the thorax, the third had two worms (one in the head and one in the thorax), and the fourth had two worms (one in the head and one in the abdomen). The caudate worms measured $240\mu \times 30\mu$ and the infective forms $350\text{–}400\mu \times 20\text{–}25\mu$.

The identity of the worms seen is of course not known; but it seems very unlikely that they were *Onchocerca volvulus* (Leuck.) since, although onchocerciasis is endemic at Lokoja, the *S. griseicolle* were not observed actually feeding on man. The 'sausage' forms seen in the *S. griseicolle* were considerably larger than those of *O. volvulus* when seen in *S. damnosum* Theobald; but a size difference in the 'sausage' stage is probably not of much significance as *O. volvulus* is normally only seen in its intermediate host at definite intervals in the development (because flies are usually only dissected after they have been caught coming to bite), whereas the *S. griseicolle* had not been collected when biting; on the other hand the infective forms observed in *S. griseicolle* were smaller than those of *O. volvulus* as seen in *S. damnosum*, which is against their being *O. volvulus*.

S. griseicolle is known to feed on birds in the Sudan[2,3,5], including turkeys and pigeons; it was noticed at Lokoja that flies sometimes occurred in small clouds around ducks. It is possible that the filarial infections seen in the flies had been derived from birds, and that *S. griseicolle* may be the vector of an avian filariasis. This possibility is supported by the recent work in Canada[6], which has shown that simuliids are the vectors of *Ornithofilaria fallisensis* Anderson, a filarial parasite of domestic and wild ducks. The fact that worms in the infective stage were found in the heads of *S. griseicolle* suggests that the fly is a vector of the parasite concerned, although the identities of the nematode and its primary host are not known as yet.

Effect of Borate Buffer on the Electrophoresis of Serum

During some recent investigations (Cooper, D. R., and Johnson, P., unpublished work), the protein components present in neutral or slightly alkaline extracts of bovine hide were compared with those of bovine serum by paper electrophoresis. For these comparisons a borate buffer ($p\text{H} = 8{\cdot}6$, $I = 0{\cdot}05$)[1] was used, and the papers were treated with bromophenol blue to detect the protein bands[2].

In several runs it was found that the intense band corresponding to albumin was preceded by a less-intense band, migrating just faster than the albumin (Fig. 1). A similar effect was also obtained with two samples of normal rat serum supplied by the South African Medical Research Institute. When barbiturate buffer ($p\text{H} = 8{\cdot}6$, $I = 0{\cdot}05$) was used instead of the borate buffer, no such effect was observed with the bovine serum. This indicates that the borate ion must increase the mobility of one or more of the components of the serum.

It is suggested that the borate ion reacts with protein-bound carbohydrate, since the band gave a positive stain for protein, resulting in an increased mobility for this component. All the protein con-

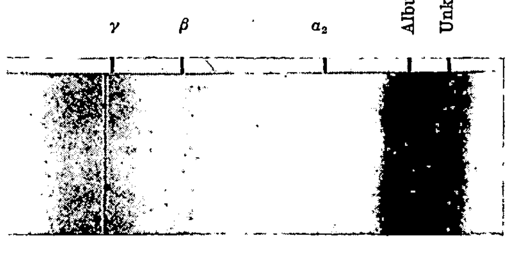

Fig. 1. Paper electrophoresis of bovine serum in borate buffer: pH 8·6; $I = 0{\cdot}05$; 0·2 m.amp./cm.; 17 hr.

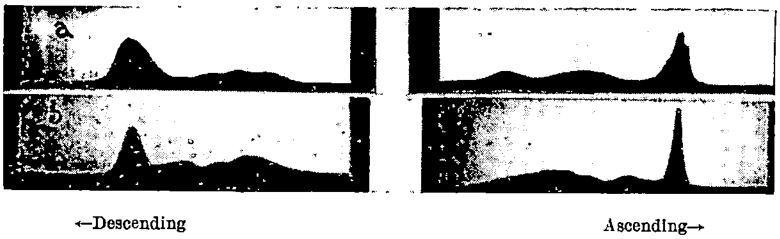

Fig. 2. Electrophoresis of bovine serum. (*b*) Barbiturate buffer, $pH = 8·6$, $I = 0·2$; (*a*) borate buffer, $pH = 8·6$, $I = 0·05$

stituents of serum appear to contain some carbohydrate, the main source being the α_1- and α_2-globulins[3]. Therefore the band obtained in borate buffer could be due to complexing between the borate ion and α_1- or α_2-globulin.

Further evidence for the effect of the borate ion on serum proteins was found by moving-boundary electrophoresis in a Tiselius apparatus at 4° C. As shown in Fig. 2, the electrophoretic pattern for bovine serum in barbiturate buffer ($pH = 8·6$, $I = 0·2$) differs considerably from that in borate buffer ($pH = 8·6$, $I = 0·05$). In the borate buffer no peak corresponding to α_2-globulin is obvious, whereas a small peak is seen to migrate just faster than the albumin in the ascending boundary, which presumably corresponds to the extra band obtained by paper electrophoresis. The albumin peak in the descending boundary is unusually diffuse and asymmetrical.

The sedimenting components of bovine serum in the two buffers were the same when examined in a 'Spinco' ultracentrifuge.

Physicochemical Investigations of Erythrocyte Membranes

A small drop of citrated human blood is placed on a slide next to a somewhat larger drop of Ponceau 2*R* and the two drops are mixed, covered with a cover glass and examined both with ordinary and polarized light. Under the double action of the dye and the hypotonicity, all the red cells become perfectly spherical with a diameter ranging from 5·0 to 5·6μ and stain weakly orange-red. No birefringence is observed.

A small drop of 1 per cent acetic acid solution or of 0·5 per cent hydrochloric acid is placed at the edge of the cover glass. As this penetrates by diffusion the red cells undergo a series of changes. Those reached by the diffusing acid first become pale and swell progressively, their surfaces being perfectly spherical. At the same time they become strongly birefringent. Most of the surface membranes form spheres of 7·5–8·5μ in diameter, while others are larger, up to 11 or even 14μ. This means a volume increase of 3·8–21·8 times the initial volume. Accompanying the swelling and the birefringence, the red cell surfaces (membranes) become stained an intense red. Some red cells show an interior concentration of hæmoglobin, and the membrane of these cells, which has no direct contact with the condensed hæmoglobin, becomes red, spherical and birefringent. In the case of other cells, the hæmoglobin is expelled while the hæmoglobin-free membrane becomes spherical and birefringent.

Sometimes, especially with stored red cells, the expulsion of the hæmoglobin through the membrane leads to the formation of a long, curved and stiff 'myelin tube' at the point at which it is expelled. This 'myelin tube' is violently projected so that the cell itself is jerked back with force and moves the other cells with which it is in contact.

The membranes of the largest empty red cells are the most birefringent, a phenomenon which is dependent upon the presence of the dye. The direction of the birefringence is tangential to the surface of the spheres.

Similarly, if a drop of 4 per cent aqueous phenol is added at the edge of the cover glass beneath which there is a red cell suspension, the erythrocytes in the contact zone between the red cell suspension and the phenol solution soon become birefringent spheres, similar to those produced by the action of the acidulated dye solution. Again, if one volume of washed red cell suspension is shaken vigorously with 20 vol. of 2·8 per cent phenol in distilled water, all the red cells lose their hæmoglobin, their membranes becoming spherical and birefringent with diameters 7·5–11μ.

Of the variety of dyes, only alkaline and acid fuchsin (1 per cent aqueous solution) behave similarly, and there seems no doubt that the birefringence of the red cell membrane is due to the oriented absorption of these dyes in concentric layers. If the red cells are hæmolysed by saponin before adding the dyes, there is no separation or birefringence of the membrane, and adding saponin to the swollen birefringent coloured membranes does not result in hæmolysis; this is probably due to the dye precipitating and fixing the protein components of the membrane. Ponceau 2*R* produces the phenomenon of swelling and birefringence of the red cell surface only if the dye solution is made acid. This is probably due to there being a close chemical combination between the lipid membrane and the interior hæmoglobin both in the normal red cell as well as in the red cell hæmolysed with distilled water, that is, to their being lipoprotein cœnapses of the type described by Rubinstein and Rudberg. While these complexes exist, the staining affinities of the lipids are marked or blocked by the protein molecules, but as soon as the bonds between the proteins and lipids are broken by hydrogen ions, valences are freed which allow the absorption of the dye and its action in fixing the protein components, thus transforming the isotopic membrane into a birefringent one. Again, the extent to which the surface structures of the red cells swell can be explained by the myelinic character of the isolated membranes, myelin forms being notoriously capable of extending their surface.

The membrane of the red cell does not seem to have a morphologically differentiated structure in that it has no cytological structure, no elasticity, mechanical resistance, etc. It appears to be fluid and unorganized, able to detach itself from its contents and to swell like any other myelin sphere consisting of fluid or semi-fluid lipids. It is highly probable that this membrane possesses a mobile statistical structure which is in a state of dynamic equilibrium with the lipids of the plasma in which the cells are suspended, lipid and protein molecules constantly leaving the red cell surface and their place being taken by similar molecules from the plasma.

Muscular Exercise and Adrenal 17-Hydroxycorticosteroid Secretion in Dogs

Evidence of increased adrenocortical secretory activity elicited by muscular exercise has been provided by indirect evaluations such as fall in ascorbic acid or cholesterol content of the adrenal gland[1–3]. However, no direct measurements of corticosteroid secretion in response to muscular exercise have been reported. The present studies were undertaken to evaluate quantitatively the effect of muscular exercise on adrenocortical activity by estimating directly the rate of secretion of adrenal 17-hydroxycorticosteroid in unanæsthetized dogs.

For collecting the adrenal venous blood under physiological condition, the lumbar route method of Satake, Sugawara and Watanabe[4] was employed. The dorsal spinal roots corresponding to the surgical operation area were cut under 'Evipan'-sodium and ether narcosis and about three weeks or more later the experiments proper were carried out. The procedures for exposing the lumbo-adrenal vein, inserting a small cannula into the vein and collecting the adrenal venous blood were performed without anæsthetizing, fastening or evoking any pain. About two hours were allowed to elapse between the cannulation and beginning observations. After collecting the control adrenal venous blood sample, the dogs, paced by an attendant on a bicycle, were run 5·1–14·7 km. at average speeds of 109–276 m. per min. In all dogs, except one, exhaustion with severe panting was observed at the end of the run. Just after and at intervals after running, the adrenal venous blood samples were taken. The plasma was separated from the blood sample by centrifugation and analysed for 17-hydroxycorticosteroids by the method of Nelson and Samuels[5].

The rate of secretion of adrenal 17-hydroxycorticosteroid before running was estimated as 0·19–0·60 μgm. per kgm. of body-weight per min., with an average of 0·34 μgm. After running, the secretion-rate was found to have increased. In one dog, which showed no signs of fatigue during and after running, only a slight increase in corticosteroid secretion was found. In four others, however, it increased markedly and reached 1·0, 1·2, 1·9 and 2·7 μgm. per kgm. per min., respectively. Maximal increase was mostly found at 60 min. after the end of the run.

Zone Electrophoresis of *Myrothrecium* Cellulase

The cellulase activity of culture filtrates of the mould *Myrothecium verrucaria* (Alb. and Schw.) Ditm. ex Fr. has been variously attributed to: (i) a single hydrolytic enzyme[1] which, *inter alia*, is homogeneous in free-boundary electrophoresis at *p*H 7; (ii) at least two and possibly three hydrolytic enzymes which migrate at different rates under the same conditions of electrophoresis[2]; and (iii) an enzyme, C_1, of unspecified function which enables cellulose to be further degraded by C_x, a group of enzymes characterized by hydrolytic activity towards carboxymethylcellulose[3], which can be resolved[4] into at least eight components by zone electrophoresis at *p*H 7. Other controversies centre on the specificity of the enzyme(s) with respect to the chain-length of cellulose and its hydrolysis products and involve certain other enzymes as well. The need to resolve these controversies prompts us to report some procedures which enable the electrophoretic homogeneity and substrate specificity of cellulases to be tested simultaneously.

The supporting media for the electrophoretic separations were strips of Whatman 3*MM* filter paper (Fig. 1), Reeve-Angel glass-fibre filter paper (Fig. 2*A*) and a thinner glass-fibre paper of very fine texture (Fig. 2*B*) obtained by courtesy of Dr. R. B. Hobbs, of the National Bureau of Standards, Washington, D.C. The enzyme preparations[1] were applied at positions indicated by dotted arrows in the figures; the amounts added were 1 mgm. of protein in 0·01 ml. of buffer when applied in one spot at the centre of the strip, 5 mgm. of protein in 0·04 ml. of buffer when applied across the width (5 cm.) of the strip as in Fig. 2*B*. Electrophoresis was carried out in a room at 3° C. with the strips of cellulose paper clamped in sets of three in an apparatus similar to that of Woods and Gillespie[5], and the glass-fibre papers in an *EC*–401 electrophoresis apparatus (E–C Apparatus Co., New York). After electrophoresis the strips were dried in a current of warm air. The solid arrows in the figures indicate the positions to which neutral components would be transported by electro-osmotic flow, as measured by the migration of trinitrobenzene or *o*-nitroaniline[6] in the cellulose paper and of glucose in the glass-fibre paper.

The strips of Whatman paper were sprayed as indicated with a 0·1 per cent ethanolic solution of

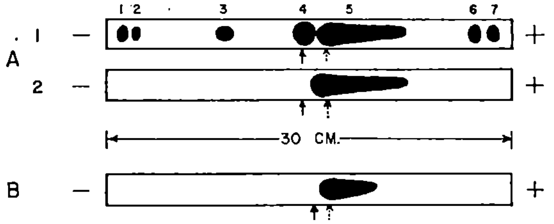

Fig. 1. Electrophoresis of crude and purified enzyme in Whatman 3*MM* filter paper.

(*A*) Crude enzyme after electrophoresis for 270 min. at a potential gradient of 14 V./cm. in phosphate buffer of *p*H 7·0 and ionic strength 0·2. Indicators: (1) ninhydrin; (2) *p*-anisidine hydrochloride

(*B*) Purified enzyme after electrophoresis for 210 min. as above. Indicator: ninhydrin

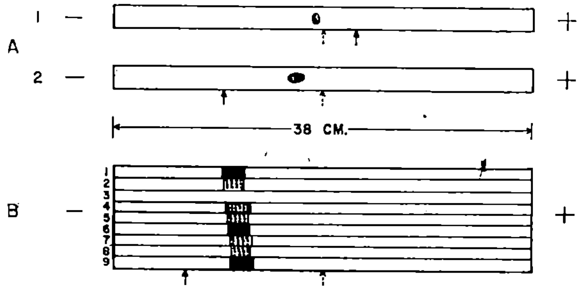

Fig. 2. Electrophoresis of purified enzyme in glass-fibre filter paper. (*A*,1) After electrophoresis for 75 min. at a gradient of 11 V./cm. in sodium acetate–hydrochloric acid buffer of *p*H 3·0 and ionic strength 0·05. (*A*,2) After electrophoresis for 90 min. at the same gradient in phosphate buffer of *p*H 6·7 and ionic strength 0·12.

(*B*) After electrophoresis for 90 min. at a gradient of 14 V./cm. in phosphate buffer as above

ninhydrin or a saturated ethanolic solution of *p*-anisidine hydrochloride and heated at 100° C. for a few minutes. Ninhydrin showed the crude enzyme to contain at least seven components, of which two (No. 4 and 5) predominated; the latter trailed as though adsorbed by the paper. *p*-Anisidine gave a typical aldohexose colour reaction which was displaced slightly in the direction of electro-osmotic flow from component 5 but conformed to its shape (Fig. 1*A*). The main change in the ninhydrin pattern after electrophoresis in acetate buffer of *p*H 5·0 was a reversal in the direction of migration of component 5; a corresponding change in the *p*-anisidine pattern was also observed. As the enzyme preparation showed no evidence of carbohydrate when tested with anthrone and gave no colour reaction with *p*-anisidine after electrophoresis in glass-fibre paper at *p*H 7 (Fig. 2*B*, strip 3) or after electrophoresis in cellulose paper at *p*H 3, we conclude that *p*-anisidine indicates reducing sugar resulting from the action of cellulase on cellulose paper during electrophoresis. Assays of cellulase activity based on the amount of reducing sugar formed when sections of a cellulose strip were incubated in acetate buffer of *p*H 5 gave a similar correlation between cellulase activity and component 5.

The glass-fibre papers to which Fig. 2*A* refers were sprayed with a 1 per cent solution of potassium permanganate in 2·5 *N* sodium hydroxide. The purified enzyme likewise showed no evidence of adsorption or heterogeneity after electrophoresis in acetate buffer of *p*H 5·0. The indicators for the individual sections in Fig. 2*B* were as follows: (*a*) alkaline permanganate (strips 1, 6 and 9); (*b*) *p*-anisidine: (i) following a spray with 0·05 *M* acetate buffer of *p*H 5·0 (strip 3); (ii) following a spray with dilute solutions of the following substrates in acetate buffer: methyl β-cellobioside (strip 8), methyl β-cellotetraoside (strip 5), cellopentaose (strip 7) and carboxymethylcellulose (Hercules Powder Co. type 50*T*) (strip 2); (iii) on Whatman No. 1 paper after strip 4 had been sprayed with buffer and left for 5 min. in close contact with the Whatman paper. The time-interval between spraying with substrate and spraying with *p*-anisidine was 20 min. for methyl β-cellobioside which, like sorbityl β-cellobioside, is hydrolysed more rapidly than cellobiose but less rapidly than cellotriose[7], and 5 min. for the other substrates. Methyl β-glucoside was not included as it is not hydrolysed by the enzyme.

This evidence of electrophoretic homogeneity in enzymatic activity toward substrates covering a wide range of degree of polymerization is in accordance with other evidence reported from this laboratory on the properties of this enzyme in hydrolysing the soluble 1,4-β linked oligoglucosides with degrees of polymerization between 2 and 6, a cellodextrin with a number-average degree of polymerization of 24 and a swollen cellulose with a weight-average degree of polymerization of 1,000[8].

The absence of polysaccharide in these enzyme preparations may be significant relative to Miller and Bloom's electrophoretic evidence of an apparent multiplicity of cellulases in an enzyme preparation containing roughly equal amounts of protein and electrophoretically heterogeneous polysaccharide[4]. Possibly *Myrothecium* cellulase, like *Stachybotrys atra* cellulase[9], forms stable complexes with polysaccharides and other metabolic products of variable occurrence in the culture medium; if so, much of the confusion in the literature on the properties of this enzyme is understandable.

A detailed report of this work will be published elsewhere.

Effect of Adenosine Triphosphate on Cleavage of Sea Urchin Eggs

THERE is no evidence for the direct participation of adenosine triphosphate in the cleavage of sea urchin eggs, although it can remove the block to division caused by certain agents such as dinitrophenol[1], and can raise the hydrostatic pressure required to prevent cleavage[2].

In a series of experiments in which the eggs of the sea urchin *Psammechinus miliaris*, from which the fertilization membranes had been removed, were placed in adenosine triphosphate (neutralized at pH 7·5–8·0) at various times after fertilization, the eggs divided normally if the concentration of adenosine triphosphate was less than 10^{-2} *M*. Eggs placed in 4×10^{-2} *M* adenosine triphosphate within 5 min. after fertilization also divided normally, but eggs placed in this concentration 40 min. after fertilization, that is, 10 min. before cleavage, showed considerable delay and abnormalities in cleavage and sometimes failed to cleave at all. The eggs often took up irregular shapes and in those which did cleave bubbling often occurred in the furrow region. The mitotic apparatus seemed unaffected and the blockage appeared partially reversible with washing.

It is very unlikely that this phenomenon is due to some greater general sensitivity of the egg just prior to cleavage, since similar tests with a wide variety of other reagents gave no indication of this.

The simplest explanation seems to be that adenosine triphosphate participates directly in cleavage (possibly through its action on the cell cortex) and that some type of regulation of the concentration of adenosine triphosphate occurs. The early application of the adenosine triphosphate allows regulation of the level of the triphosphate to occur, but the addition of a high concentration of adenosine triphosphate close to the time of cleavage gives no opportunity for regulation to occur and causes inhibition.

It was also found that isotonic calcium chloride reversibly inhibits cleavage if applied just before cleavage starts ; also, eggs placed in isotonic magnesium chloride after fertilization usually cleave with a very characteristic bubbling in the furrow region.

There is good evidence that cleavage involves a contractile system[3,4], and these results suggest that it may be in some ways analogous to an actomyosin system in which superoptimal concentrations of adenosine triphosphate can inhibit contraction and in which behaviour of the system is very dependent on the relative concentrations of adenosine triphosphate, calcium and magnesium. A similar system is involved in the cleavage of the glycerol-extracted models of tissue-culture cells of Hoffmann-Berling[5].

A paper on the relevance of these results to a detailed theory of cleavage is in preparation[4].

This work was carried out at the Marine Station, Millport, while holding a Nuffield Biological Scholarship.

Nitrogen Fixation in *Elaeagnus* Root Nodules

The three genera comprising the Elaeagnaceae, namely, *Elaeagnus*, *Hippophaë* and *Shepherdia* have been known for some time to bear root nodules ; but it is only within the past few years that the physiological significance of these structures has been rigorously investigated. Previously, the main interest had been cytological. Nodules of *Hippophaë*[1,2] and *Shepherdia*[3] have recently been shown, by growth experiments and by tests with nitrogen-15, to be able to fix nitrogen.

The genus *Elaeagnus* comprises 30 species widely distributed in Asia, Europe, and North America. Nobbe and Hiltner[4] reported that a nodule-bearing plant of *E. angustifolia* showed marked ability to grow in sand free of combined nitrogen, and attained a height of 120 cm. in four years as compared with 24 cm. for a corresponding plant without nodules. The authors accordingly suspected the occurrence of fixation. Roberg[5] reported that, in the course of tests which demonstrated cross-inoculation between *Elaeagnus* and *Hippophaë*, he saw signs of fixation in both genera, while Panosjan[6], whose report is available only in summary form, found that nodulated plants were independent of the presence of combined nitrogen.

In the present work, seed of *E. angustifolia* was germinated in moist sand in the spring of 1956 and the seedlings grown on in water culture in Crone's solution containing a small quantity of combined nitrogen. After four weeks, a nitrogen-free solution was substituted and a suspension of crushed nodules from a plant of *E. pungens* growing in the Glasgow Botanic Gardens (obtained by the kindness of the Curator) was applied to the roots of certain of the plants. Since no nodules had appeared after 4 weeks, it seemed that the inoculum had been inactive, and a further inoculum, prepared from *Hippophaë* nodules, was applied. After ten days, numerous nodules were present on the roots of the plants in culture solution of pH 6·0, but none at pH 5·0.

Growth of the plants was allowed to continue until autumn 1957, with periodic renewal of the nitrogen-free culture solution. Control plants without nodules showed very feeble development, but nodulated plants grew satisfactorily (Fig. 1) and accumulated substantial amounts of nitrogen (Table 1). The mean percentage nitrogen (dry weight basis) in the nodules was 3·5 as compared with 1·8 in both roots and shoots.

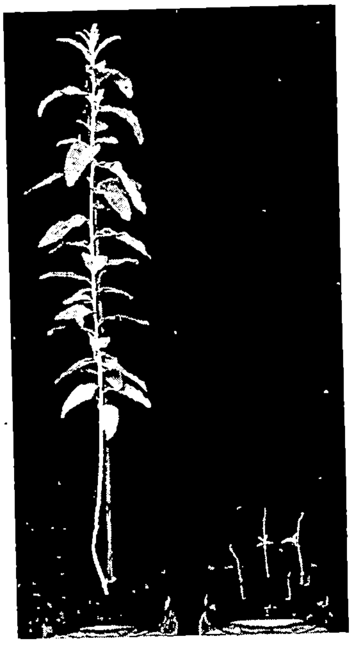

Fig. 1. Plants of *Elaeagnus angustifolia* after two seasons growth in culture solution free of combined nitrogen. The plant on the left bears root nodules. $\times \frac{1}{8}$

Table 1. HARVEST RESULTS FOR *Elaeagnus angustifolia* AFTER 15 MONTHS GROWTH IN NITROGEN-FREE CRONE'S SOLUTION

Type	Plant No.	Shoot height (cm.)	Dry weight (gm.) Root+Shoot	Dry weight (gm.) Nodules	Total nitrogen (mgm.)
Nodulated	1	43	2·22	0·11	27·0
	2	62	6·59	0·21	148·8
	3	56	5·84	0·19	128·0
	4	74	9·64	0·40	186·4
Non-nodulated	5–8	4–10	0·03–0·15	—	0·5–2·1

Although the plants were not grown under aseptic conditions, the only satisfactory explanation of the strong growth of the nodulated plants is that the nodules are able to fix nitrogen. It is reasonable to suppose that the same is true of the nodules of other species of *Elaeagnus*. Evidence[7,8] is growing that the ecological importance of non-legume nodule plants such as *Alnus*, *Myrica* and *Hippophaë* in the provision of soil nitrogen in past and present times is greater than previously supposed. The same may apply to *Elaeagnus*.

Vesicular-Arbuscular Mycorrhiza in the Gramineae

VESICULAR-ARBUSCULAR mycorrhiza has been found to be widespread in cereals and in many grasses in Britain[1]. The incidence of root infection and the amount of endophyte mycelium on the root surface and in the rhizosphere differ greatly in different habitats and communities. For example, in sand-dune grasses—where mycorrhiza is strongly developed —the degree of infection varies between different species and with the stage in the dune succession. As illustrated in Table 1, samples collected from the sand dunes at Gibraltar Point, Lincolnshire, showed about a 20 per cent level root infection when growing in the embryo dune phase, that is on sites which have never supported plant growth previously. In the next zone in the dune succession infection falls almost to zero, but it reaches a maximum where the sand becomes stabilized in the fixed yellow dunes. In this zone, where the ranges of three grasses overlap, there is marked variation in infection between the different species. As the community matures and becomes more complex, there is a general decrease in endophyte activity. Roots of grasses in the fixed yellow dunes were often extensively covered with wefts of external mycelium as well as showing a high incidence of infection.

Table 1

Vegetation zone	Species	Root infection (per cent)	Roots with external mycelium attached (per cent)
Embryo dunes	*Ammophila arenaria*	19	15
Mobile yellow dunes	*Ammophila arenaria*	1	2
Fixed yellow dunes	*Ammophila arenaria*	37	43
	Festuca rubra var. *arenaria*	45	22
	Poa pratensis	18	20
Older fixed dunes	*A. arenaria*	6	0
	P. pratensis	3	0·5

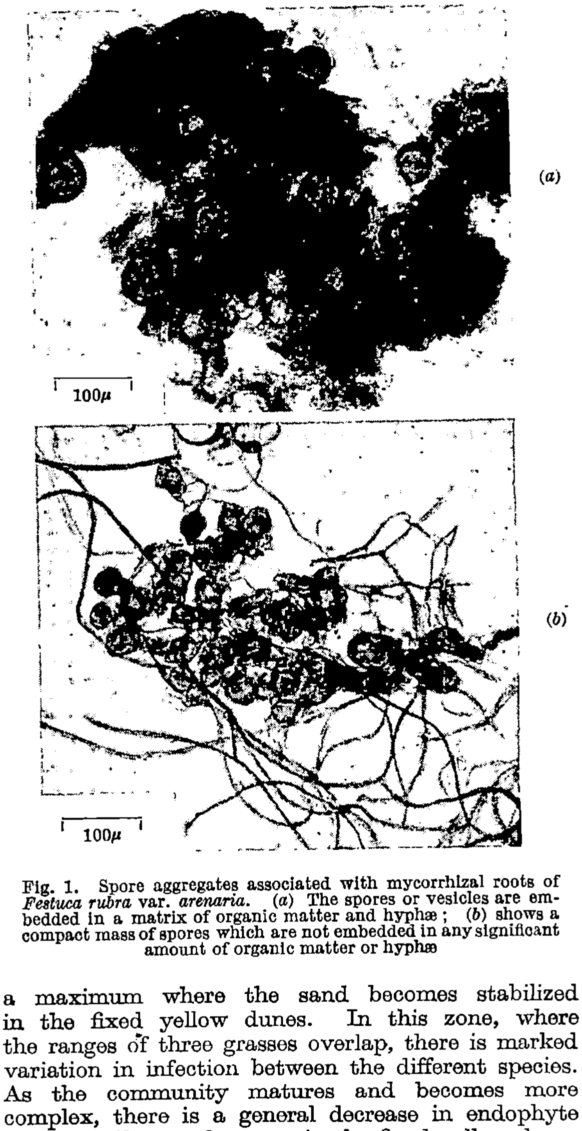

Fig. 1. Spore aggregates associated with mycorrhizal roots of *Festuca rubra* var. *arenaria*. (*a*) The spores or vesicles are embedded in a matrix of organic matter and hyphæ; (*b*) shows a compact mass of spores which are not embedded in any significant amount of organic matter or hyphæ

Compact aggregates of spores, resembling *Endogone*-type fruiting bodies, have been found on external mycelium associated with, and directly connected to, the endophytic mycelium in the roots of *Festuca rubra* var. *arenaria* and *Ammophila arenaria*. These spore masses are not as regular or uniform in size or structure as the sporocarps described by Mosse[2,3]. In size the spore aggregates on grass roots vary greatly but they are always less than 0·8 mm. diam. Three main types of structure occur: (1) the spores or vesicles may be embedded in a matrix consisting of hyphæ and some organic matter (Fig. 1*a*); (2) the spores may be embedded in a matrix of organic matter with little or no hyphæ present—many particles or organic matter which remain attached to the external mycelium or to the root surface after gentle washing contain embedded spores in this way; or (3) there may be compact masses of spores which are not embedded in any significant amount of hyphæ or organic matter (Fig. 1*b*). These different conditions possibly represent developmental or disintegration stages of distinct fruiting bodies or may be due to strain differences in the endophyte. The number of spores present varies greatly, and up to 50 have been noted in a single structure. Likewise there is variation in size of spore, the largest seen being 75μ in diameter. Frequently these spores have thick walls (Fig. 1*a*); otherwise they resemble isolated vesicles formed on external mycelium.

These observations, which include samples from a wide range of habitats, suggest that the endophytes occurring on grasses in the majority of cases are related to the genus *Endogone*, being similar to those described on a range of different plants by Peyronel[4,5] and on fruit plants by Mosse. No evidence has yet been obtained that the endophytes of grasses may be strains of *Pythium ultimum* as has been found for vesicular-arbuscular mycorrhiza in *Allium ursinum* and in other plants[6-8].

I am grateful to Dr. Barbara Mosse of the East Malling Research Station for allowing me to inspect her *Endogone* material.

The Vitreous Body of *Galago crassicaudatus agisymbanus*

MANY aspects of the anatomy of the eye in galagos and related species have been described[1,2]. I am, however, not aware of any description of the vitreous body in these species, but in *Galago crassicaudatus agisymbanus* I have found peculiarities that I have not encountered or found described in other animals.

In vertebrates the vitreous body is generally described as a translucent gel, although its consistency varies, being most rigid in birds[3] and varying considerably in solidity among the mammals. Examination with the slit-lamp, dark-ground and phase-contrast microscopes shows that it possesses a definite structure[1,3].

The vitreous body of *Galago c. agisymbanus*, however, is in ordinary circumstances a free liquid. Thus it can be aspirated through a hypodermic needle of 0·3-mm. external diameter as easily as can the aqueous humour, the volume extracted varying between 0·8 and 1·0 ml. and leaving the globe almost empty. The fluid so extracted shows no tendency to clot and contains only a trace of substance precipitated by trichloracetic acid.

The vitreous body in this species would also appear to be structureless on examination with the slit-lamp microscope, although it must be said that good definition is very difficult in this animal because of the intense reflexion from the highly developed cellular tapetum.

The vitreous body is generally believed to exchange constituents with surrounding tissues and fluids, especially the aqueous humour, solely by diffusion of substances, and not by any mechanical mixing with other fluids or by stirring of the liquid phase of the vitreous body itself[4,5]. This fact has recently been shown to be of importance in investigating the dynamics of the exchange of substances within the rabbit's eye[5].

The following experiments were carried out on the galago in view of the apparent species differences and the implications they carry. The animal was anæsthetized (sodium pentobarbitone 30 mgm./kgm.), placed prone with the head held in a mould so that the plane of the lens of the eye was approximately horizontal. The eye was atropinized and a 0·3-mm. external diameter hollow needle pushed through the sclera at the equator until the point could be clearly seen under the lens in the centre of the vitreous, either by the naked eye with good general illumination or with the ophthalmoscope. With a micrometer syringe attached to the needle by 'Polythene' tubing, 0·001–0·002 ml. of indian ink suspended in physiological saline was injected into the eye. The needle was withdrawn, detaching the droplet, which fell smoothly and freely through the vitreous on to the fundus, where it spread over the surface, clearly visible against the brilliant gold of the tapetum. It dispersed, leaving no area of obviously high concentration, within 15–20 min.; an attempt to repeat the experiment *in vitro*, with a similar droplet falling and mixing in saline, gave a dispersion time of the same order. If the eye was manipulated or the head moved briskly during the observation, the time for dispersion was reduced to about 7 min. No definite streams of flow were seen, nor can any circulation of the vitreous be argued from the experiments; but it is almost certain that the vitreous in this species in ordinary circumstances is a homogeneous fluid, probably kept stirred by the normal head and eye movements. It should also be noted that these experiments provide no evidence of a mingling of the aqueous and vitreous fluids. There is in fact good evidence that the fluids are quite separate. Aspiration of the vitreous does not withdraw any fluid from the anterior chamber, nor does the anterior chamber fill rapidly after aspiration of the aqueous humour which one might expect if there was free mixing of the fluids. Even if this evidence is insecure, as one might suppose the possibility of an iris-lens valve mechanism that prevented flow into or out of the anterior chamber under abnormal pressure, there is the further fact that particulate matter in the form of indian ink suspended in aspirated vitreous fluid and reinjected does not appear in the aqueous humour even after vigorous movements of the head and eye.

Size and Shape of Alfalfa Mosaic Virus

In the course of purifying alfalfa mosaic virus we have found that at least three kinds of macromolecular particles are produced by plants as a result of their infection with the virus, and that one of these is the infectious entity. In the electron microscope the virus particles, and also the other two particles, appear as small rodlets about 550 A. long and about 200 A. in diameter. Thus they are not spherical, as previous isolates of alfalfa mosaic virus apparently are, and indeed they look markedly different from any viruses reported in the literature.

The isolate used was obtained from ladino clover. Single local-lesion isolates were made from bean, one of which was retained and identified by cross protection tests to be similar to isolate No. 96 of the American Type Culture Collection[1]. It is similar in symptomatology and concentration pattern to the unobtainable alfalfa mosaic virus isolate extensively studied by Ross[2]. The virus was grown on *Nicotiana tabacum* L. var. 423[1] and purified using methods similar to those described by Ross. Alternative methods involving differential centrifugation and *n*-butanol chloroform–water extraction[3] at 6° C. yielded purified material with similar specific infectivity.

These purified preparations exhibited three closely spaced schlieren peaks in the analytical ultracentrifuge with sedimentation coefficients at infinite dilution and 20° C. of 73, 89 and 99 Svedberg units. The buffer was 0·10 ionic strength of which 0·08 was contributed by sodium chloride and 0·02 by sodium phosphates. The areas under the schlieren peaks were in the ratio 43 : 14 : 43 for top, middle and bottom components respectively. No such peaks were observed in similarly prepared extracts from healthy plants. From its sedimentation behaviour, this material does not appear to be similar in its physical properties to Ross's isolate, since his material under similar preparative conditions yielded a single sedimentation peak with a sedimentation constant of $S_{20,w} = 70\,S$.

The three components were partially separated from each other using sucrose density-gradient centrifugation techniques in a 'Spinco' *SW* 25 swing bucket rotor[4,5]. Complete separations were not achieved because the resulting three bands were very closely spaced. In one experiment three fractions were obtained for electron microscopy, sedimentation and infectivity tests. Fraction 1 removed from the topmost band contained more than 90 per cent top component and less than 5 per cent middle and 5 per cent bottom components. Fraction 2 removed from the middle band contained about 30 per cent top, 50 per cent middle and 20 per cent bottom component. Fraction 3 removed from the bottom band contained more than 90 per cent bottom component and less than 5 per cent middle and 5 per cent top components. All three fractions were serologically similar and gave identical ultra-violet absorption curves, with a maximum at 260 mμ.

Their relative infectivities were tested by assaying on the local-lesion host *Phaseolus vulgaris* L. var. Bountiful. Fraction 1 gave 5 lesions, fraction 2 gave 405 lesions and fraction 3, containing predominantly bottom component, gave 1,900 lesions. Clearly, infectivity is associated with a particle having the sedimentation characteristics of the bottom component. The residual infectivity in fraction 1, and probably also in fraction 2, could be attributed to contamination with bottom-component particles.

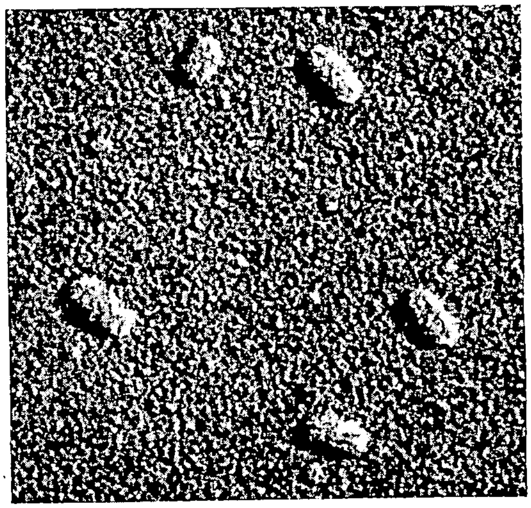

Fig. 1. A uranium-shadowed preparation of fraction 3, taken in a Siemens Elmiskop I. (× 140,000)

Electron microscope specimens were prepared using essentially the freeze-drying method of Williams[6]. Micrographs of the three fractions were indistinguishable, and all showed particles most of which had a minor dimension of about 240 A. and the majority of which had a major dimension of about 550 A. Fig. 1 is a typical micrograph of fraction 3, that is, the bottom component. Fig. 2 shows the length distribution of 100 particles lying in the proximity of the particles of Fig. 1. It shows that some short particles exist, whereas only a few are longer than 600 A.

As is the case with shadowed tobacco mosaic virus and with other elongated viruses[7], centre-to-centre distances between several particles lying side-by-side is less than the measured width of isolated particles. The former is probably the more accurate measure of particle diameter. The average centre-to-centre distance measured in this work is about 200 A. Thus the predominantly occurring macromolecular particle in our virus preparation is a short rod about

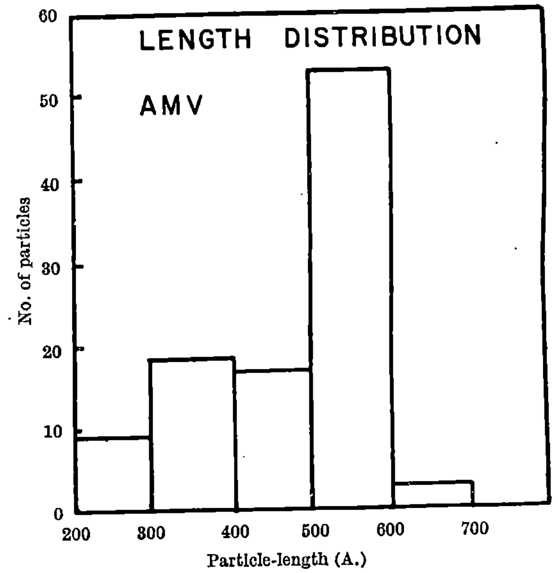

Fig. 2. The length distribution of 100 particles lying in the proximity of particles of Fig. 1

200 A. in diameter and 550 A. in length. The predominant particles in the top and middle component preparations have similar dimensions.

This work was supported in part by the Public Health Service and by the Research Committee of the University of Wisconsin Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

Virus Transmission by *Dactynotus cichoricola* H.R.L., a New Aphid on Chicory

A SHINY, dark brown, rapidly multiplying aphid was observed in the early autumn of 1957 on *Cichorium intybus* L. var. *foliosum* cultivated as a vegetable in fields near Louvain (Belgium). Later, the insect was found on the same crop in several other places. The species, which is close to *Dactynotus tussilaginis* Wlk., was acknowledged as new by M. Hille Ris Lambers (Bennekom, Netherlands), and named by him *Dactynotus cichoricola* n. sp. In September, apterous and alate virginoparæ, unwinged oviparous females and apterous males were captured, while in October only the last two forms could be found.

Copulation of *D. cichoricola* is common under laboratory conditions; the eggs are shiny black when 1–2 days old. Oviposition takes place on the stalks and on the lower face of the leaves. Under natural conditions, some eggs were found on *Cichorium intybus*. Trials were conducted to determine whether this aphid is a vector of plant viruses. Only one aphid-borne virus, namely, cucumber mosaic virus[1,2] is known on chicory.

Young larvæ of oviparous females of *Dactynotus cichoricola*, collected on chicory in an open field, were reared in the laboratory on *C. intybus* seedlings until they were adult. They were then starved for 2–3 hr. and allowed to feed for 1 min. on tobacco leaves infected with a cucumber mosaic strain isolated from chicory. Many of them did not insert their stylets in the leaf tissues, although they had the typical feeding aspect; these were removed. The remainder were immediately transferred to the test-plants for 24 hr.

Of three inoculated cucumber seedlings var. Blanc hâtif (ten aphids on each plant), two showed the typical symptoms of the virus after 8 days. Control plants inoculated with non-infectious aphids remained unaffected.

Of three inoculated tobacco seedlings var. Samsun (five aphids on each plant), two became infected with the virus as was shown by the symptoms and by a protection test against Pierce's yellow strain of cucumber mosaic virus.

Not one of six aphid-inoculated chicory seedlings var. *foliosum* (five aphids on each plant) became infected, but two of five plants showed the typical symptoms of the virus when inoculated with infectious tobacco sap mixed with 'Carborundum'. These results agree with the very low infection-rate of chicory cultures by cucumber mosaic virus.

The same method was used with aphids fed for 1 min. on beet leaves infected with beet mosaic virus and transferred to three young beet seedlings var. Kleinwanzleben E. (five aphids on each plant). The symptoms of the virus infection became apparent on one of the beets after 13 days.

It was observed that most of the chicory leaves colonized by *D. cichoricola* in the field showed brittle areas with interveinal yellowing and thickening. Sap inoculation, and aphid transmission trials with *Myzus persicae* Sulzer, *Myzus ascalonicus* Doncaster and *Dactynotus cichoricola* H.R.L. were made from those leaves on to chicory seedlings, but no reliable results were obtained to support the idea that the symptom is associated with a virus.

I thank Prof. R. Vanderwalle for his helpful criticism during the experiments. Virus-infected material sent by Mr. F. C. Bawden, Rothamsted Experimental Station, and Dr. K. M. Smith, University of Cambridge, is gratefully acknowledged.

Relationship of Tectoquinone to Durability in *Tectona grandis*

THE heartwood of teak (*Tectona grandis* L.f.) is extremely resistant to attack by insects or by fungi; but the reasons for this resistance are not known. It is usually ascribed to the presence of toxic substances, and it has been suggested that tectoquinone (β-methyl anthraquinone), which is characteristically present in teak heartwood, may be responsible. Wolcott[1] has shown this substance to be highly repellent to the dry-wood termite *Cryptotermes brevis* (Walker), and Sandermann and Dietrichs[2] have demonstrated its toxicity, in high concentrations, to the North American subterranean termite *Reticulitermes flavipes* Kol. No reference seems to have been made to its toxicity to fungi. In current investigations into the chemical basis of the durability of teak, we have examined the amount of tectoquinone in teak from Thailand and Indonesia, and its toxicity to decay fungi and to subterranean termites.

Tectoquinone was readily identified on paper chromatograms by its bright green-yellow fluorescence in ultra-violet light. It was observed at R_F 0·90 in *n*-butanol/acetic acid/water (6 : 1 : 2) at 20° C.; anthranilic acid, used as a marker, was located at R_F 0·85 under these conditions. Using *n*-butanol saturated with an ammonia buffer (Fewster and Hall[3]), tectoquinone had an R_F value of 0·94, while benzoic acid, used as a marker, had an R_F value of 0·44. The tectoquinone present in several samples of

Table 1. Tectoquinone Content and Durability of Teak Blocks

	Tecto-quinone (per cent)	Decay		Termite attack	
		C. cerebella	*T. lilacino-gilva*	*C. lacteus*	
		Weight-loss (per cent)	Weight-loss (per cent)	Weight-loss (per cent)	Survival* (per cent)
Teak 1 (Thailand)					
Outer heartwood	0·58	0·9	2·0	4·8	73
Middle heartwood	0·29	3·3	8·1	5·7	69
Inner heartwood	0·12	17·8	34·2	13·2	73
Teak 2 (Indonesia)					
Outer–middle heartwood	0·11	1·1	1·2	18·0	66
Mountain ash heartwood (control)	—	45·6	57·8	100·0	65
Unfed control termite colony	—	—	—	—	68

Each result is the mean of five blocks for fungi and eight for termites.

* All *C. lacteus* colonies (including unfed control) survived for the whole of the test (84 days); survival (per cent) is given on the 84th day.

teak was isolated by thorough extraction of the sawdust with ether followed by methanol; partial purification was carried out by paper chromatography and alkali washing. The tectoquinone was estimated by conversion to the sodium salt of dihydro-tectoquinone, and the absorption at 417 mμ (max.) compared with standards of this derivative made from pure tectoquinone (B.D.H., Ltd.). The results are given in Table 1 and show that the amount of tectoquinone in durable outer heartwood was as high as 0·58 per cent (oven-dry basis). Kafuku and Sebe[4] have isolated 0·3 per cent of tectoquinone from teak heartwood and recently Sandermann and Dietrichs[2] have isolated 0·36, 0·56 and 0·88 per cent from Indonesian, Thai and Burmese teak respectively.

The amount of tectoquinone present in different samples of teak was then compared with the resistance of matched test blocks to attack by the wood-destroying fungi *Coniophora cerebella* Pers. DFP 1779 and *Trametes lilacino-gilva* Berk. DFP 1109 and by the subterranean termite *Coptotermes lacteus* (Frogg.). The resistance of the test blocks to decay was measured by a soil-wood block decay test[5], and termite resistance was measured by the standard laboratory colony test of Gay *et al.*[6]; these results are given in Table 1.

To determine the toxicity of tectoquinone to wood-destroying fungi, known amounts of pure tectoquinone (B.D.H.) were dissolved in ether and added to known amounts of decay-susceptible sawdust from the heartwood of mountain ash (*Eucalyptus regnans* F. Muell.). The methanol was removed by vacuum-drying and 0·5-gm. samples of sawdust tested for decay resistance in the soil jar–sawdust dish technique described by Da Costa and Rudman[7]. The results (Table 2) show no evidence of toxicity even at concentrations well above those found in teak. (These two test fungi, under similar conditions of test, will not produce weight losses of more than 3 per cent in sawdust from durable teak heartwood.)

Table 2. Effect of Tectoquinone in Mountain Ash Sawdust on Decay Fungi

Tectoquinone in mountain ash (per cent)	*C. cerebella* Weight-loss (per cent)	*T. lilacino-gilva* Weight-loss (per cent)
0·00	44·8	23·4
0·05	47·4	23·5
0·10	49·1	21·5
0·20	47·0	23·6
0·40	48·4	22·2
0·80	46·8	23·4
1·60	44·6	22·0

Each result is the mean of four replicates

The toxicity of tectoquinone to termites was determined by dissolving known amounts in benzene and mixing the solution into 100-gm. samples of mountain ash sawdust. The sawdust was bonded with melamine powder under pressure into a compact board, the temperature being maintained at 70° C. for the first ½ hr. of the 24-hr. pressing period. Test samples, approximately 3½ in. × ½ in. × ½ in., were sawn from these boards and tested in standard laboratory termite colonies of *C. lacteus* and of *Nasutitermes exitiosus* (Hill); the results are given in Table 3. Although the progressively smaller amounts eaten (weight-loss) with increasing loadings indicate that tectoquinone is distasteful and/or nutritionally unsatisfactory to these termites, the amount of attack is far greater than that obtained on samples of durable teak heartwood of smaller tectoquinone content. Comparison of survival-rates with those of the unfed colonies indicates that there is no actual toxic effect.

Table 3. Effect of Tectoquinone in Mountain Ash Sawdust on Subterranean Termites

Tectoquinone in mountain ash (per cent)	*C. lacteus*		*N. exitiosus*	
	Weight-loss (per cent)	Survival (per cent)	Weight-loss (per cent)	Survival (per cent)
0·00	83·4	56·9	90·4	40·0
0·30	68·1	61·0	75·6	37·5
0·60	31·5	55·0	50·7	29·1
1·20	15·3	60·6	16·2	0·0*
Unfed control colony	—	57·7	—	0·0†

Each result is the mean of three, except for unfed control which is the mean of two. Duration of test: 84 days.

* Colonies only survived a mean of 54 days.

† Colonies only survived a mean of 50 days.

In general, it may be concluded that although tectoquinone occurs in appreciable quantities in teak heartwood, it shows no sign of toxicity to wood-destroying fungi; its effect on subterranean termites is relatively slight, and it is not solely responsible for the termite resistance of teak.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, March 10

University College, London (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Dr. J. D. Judah: "Oxidative Phosphorylation".* (Further lecture on March 17.)

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Sir William Pugh, O.B.E., F.R.S.: "The Geological Survey of Great Britain". (First of two Cantor Lectures. Further lecture on March 17.)

Institution of Electrical Engineers, London Graduate and Student Section (joint meeting with the Institution of Civil Engineers, at Great George Street, London, S.W.1), at 6.30 p.m.—Vice-Admiral Sir Archibald Day, K.B.E., C.B., D.S.O.: "The International Geophysical Year".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Prof. P. M. S. Blackett, F.R.S.: "Rock Magnetism as Evidence of Continental Drift".

Tuesday, March 11

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Scientific Papers.

Institution of the Rubber Industry, London Section (at the National College of Rubber Technology, Holloway, London, N.7), at 5.30 p.m.—Mr. E. Hornby: "Modern Methods of Tyre Building and Vulcanizing". 7 p.m.—Research Lecturers and Demonstrations.

Tuesday, March 11—Wednesday, March 12

Society of Chemical Industry, Corrosion Group (at the Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London, S.W.1), at 9.30 a.m. daily—Symposium on "The Protection of Motor Vehicles from Corrosion".

Tuesday, March 11—Thursday, March 13

Oil and Colour Chemists' Association, London Section (in the Royal Horticultural Society's New Hall, Greycoat and Elverton Streets, London, S.W.1)—Tenth Technical Exhibition.*

Wednesday, March 12

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. N. W. Pirie, F.R.S.: "World Hunger as a Biochemical Problem" (Frankland Armstrong Memorial Lecture).

Palæontological Association (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 4.45 p.m.—Prof. O. M. B. Bulman, F.R.S.: "The Sequence of Graptolite Faunas" (First Annual Address).

Royal Institution, Library Circle (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Dr. H. D. Anthony: "Scientific Books of the 18th Century and the Emergence of Modern Science".

Institute of Welding (at 54 Princes Gate, Exhibition Road, London, S.W.7), at 6 p.m.—Prof. Sir Alfred Pugsley, F.R.S.: "The Influence of Welding on Structural Design".

Society of Chemical Industry, Food Group (joint meeting with the Microbiology Group, at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Meeting on "The Prevention of Microbial Spoilage in Fruit".

Radar and Electronics Association (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 7.30 p.m.—Prof. A. C. B. Lovell, O.B.E., F.R.S.: "The Jodrell Bank Radio-telescope in Action".

Thursday, March 13

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion on "The Physiology and Biochemistry of Lactation".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. T. G. Tutin and Dr. V. H. Heywood: "The Flora Europaea Project"; Dr. J. Ramsbottom, O.B.E.: "P. A. Micheli's *Nova Plantarum Genera*, 1729".

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. L. Smart and Mr. J. J. L. Weaver: "The Use of Steel-Tank Mercury-Arc Inverters for Generating Medium Frequencies for Induction Heating".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Kurt Mothes (Deutsche Akademie der Wissenschaften zu Berlin): "Physiology of Alkaloids".* (First of two Special University Lectures in Pharmacy. Further lecture on March 14.)

Royal Institute of Chemistry, London Section (joint meeting with the West Ham College of Technology Chemical Society, at the West Ham College of Technology, Romford Road, London, E.15), at 7 p.m.—Mr. I. Goodman: "The Chemistry of Synthetic Fibres".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Prof. Dr. W. Klemm: "Metalloids and Their Compounds with the Alkali Metals" (Centenary Lecture).

Friday, March 14

Society for Water Treatment and Examination (at the Royal Society of Health, 90 Buckingham Palace Road, London, S.W.1), at 9.30 a.m.—Annual General Meeting, followed by Scientific Papers.

Royal Institute of British Architects (in the Jarvis Hall, R.I.B.A., 66 Portland Place, London, W.1), at 2.15 p.m.—Symposium on "The Design of Teaching Laboratories in Universities and Colleges of Advanced Technology".

British Glaciological Society (at the Geography School, 341 Bristol Road, Birmingham), at 5.30 p.m.—Mr. W. H. Ward: "The Ice Caps and Glaciers of Baffin Island".

Institute of Physics, Non-Destructive Testing Group (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Meeting on "X-Ray Microscopy". Prof. R. W. K. Honeycombe: "Surfaces Reflection Techniques"; Mr. P. Duncomb: "Electron Probe Methods".

Society of Chemicals Industry, Fine Chemicals Group (joint meeting with the London Section, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. E. S. Hedges and Dr. G. J. M. Van der Kerk: "Research on Organotin Compounds and their Technological Applications".

Royal Photographic Society (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Mr. S. W. Simmons: "Kinematograph Instrumentation".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. H. S. W. Massey, F.R.S.: "Artificial Satellites".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (with a degree in science or agriculture and an interest in dairy chemistry) in Chemistry—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (March 13).

Assistant, Grade B, for Anatomy, Physiology and some Biology; an Assistant, Grade B, for Chemistry and Science; and an Assistant, Grade A, for General Laboratory Techniques and Science—The Secretary, Paddington Technical College, Saltram Crescent, London, W.9 (March 14).

Assistant Librarian (Chartered Librarian) in the Dairy Science Library—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 58/4 (March 15).

Lecturer in Organic Chemistry—The Principal, Nottingham and District Technical College, Shakespeare Street, Nottingham (March 15).

Lecturer (Grade II) in Pure Mathematics—The Registrar, The University, Bristol (March 17).

Scientist (with a good honours degree or equivalent in chemistry, chemical engineering or metallurgy and a number of years experience in a responsible position in industrial research, development or production operations, and preferably experience in uranium or ceramics), at Springfields Laboratory, Salwick, Preston, Lancashire, to lead a section which is principally concerned with the experimental manufacture of ceramic fuels—The Recruitment Officer, United Kingdom Atomic Energy Authority, I.G.H.Q., Risley, Warrington, Lancashire, quoting Ref. 2289 (March 17).

Head (with good academic and teaching qualifications and preferably industrial experience) of the Mathematics Department—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (March 20).

Assistant Curator (Ethnology) (with a good honours degree or diploma and preferably museum experience) at Horniman Museum, London, S.E.23—The Education Officer (EO/Estab.2/F), The County Hall, London, S.E.1 (March 21).

Junior Lecturer in Physical Chemistry—The Registrar, Trinity College, Dublin (March 22).

Assistant Lecturer and Demonstrator in Zoology—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (March 24).

Assistant Lecturer (with qualifications in petrology) in Geology; and an Assistant Lecturer (with qualifications in pure mathematics) in Mathematics—The Registrar, The University, Hull (March 28).

Assistant Lecturer or Lecturer in Pure Mathematics—The Registrar, University College, Singleton Park, Swansea (March 29).

Experimental Officers (with a degree in horticulture or botany or equivalent) in the Pomology Section, for (*a*) experiments on propagation of fruit plants, and (*b*) field experiments on small fruits—The Secretary, East Malling Research Station, near Maidstone, Kent (March 31).

Keeper (with a university degree in botany or zoology or the Diploma of the Museums Association, and previous museum experience) of the Department of Biology in the Leicester Museums—The Director, Museums and Art Gallery, New Walk, Leicester (March 31).

Lecturer in Psychology at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, March 31).

Post-Doctoral Fellow in Chemistry, for work on thermodynamic and relaxation behaviour of polyblycol-solvent systems—Dr. B. E. Conway, Department of Chemistry, University of Ottawa, Ottawa, Canada (March 31).

Research Fellow in the Chemistry Department, for fundamental work on compounds potentially useful in the paint industry—The Professor of Chemistry, The University, Hull (March 31).

Lecturer (with a degree in agriculture and a specific interest in animal husbandry generally and poultry in particular) at Gwebi Agricultural College (Ministry of Agriculture), Salisbury, Southern Rhodesia, for duties which will include lecturing and giving practical instruction to diploma students in certain aspects of animal husbandry, including anatomy, physiology and in poultry husbandry—The Secretary (R), Rhodesia House, 429 Strand, London, W.C.2 (April 1).

Lecturer/Senior Lecturer (preferably with a principal interest in morphological, physiological or chemical cytology) in Histology and Embryology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 5).

Lecturer (with an honours degree in engineering or physics and experience in vacuum tube and transistor circuits) in Electrical Engineering at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 5).

RESEARCH OFFICER (qualified zoologist with experience of fisheries research) IN THE FISHERIES RESEARCH UNIT within the Department of Biology, University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong, April 8).

UNIVERSITY STUDENTS AND FELLOWS, for experimental or theoretical research in nuclear and elementary particle physics—The Professor of Natural Philosophy, The University, Glasgow, W.2 (April 12).

SENIOR LECTURER (with a degree in science with geology as a major subject, and experience in modern mineralogical techniques) IN GEOLOGY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 30).

TURNER and NEWALL RESEARCH FELLOWS IN ENGINEERING, INORGANIC CHEMISTRY, PHYSICS and allied subjects—The Registrar, The University, Manchester 13 (April 30).

PRINCIPAL (graduate of a university in the British Commonwealth, a wide experience of agricultural teaching or advisory work, experience of administration and a sound knowledge of commercial agriculture, and preferably under 45 years of age) OF THE ROYAL AGRICULTURAL COLLEGE—Joint Clerks to the Governors, Royal Agricultural College, 7 Dollar Street, Cirencester, Glos (May 1).

SENIOR TECHNICIAN or TECHNICIAN IN THE DEPARTMENT OF CHEMISTRY, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 2).

ASSISTANT CHEMIST (male or female, with training in agricultural chemistry, and preferably postgraduate experience), to carry out investigations into matters concerning turf maintenance—The Secretary, The Sports Turf Research Institute, Bingley, Yorkshire.

CHIEF PLANT PHYSIOLOGIST in the Division of Plant Industry, Department of Agriculture and Stock, Brisbane, Australia—Agent-General for Queensland, 409 Strand, London, W.C.2.

ENGINEERS AND PHYSICISTS (with an honours degree), for work in Sheffield on problems of metal plasticity, lubrication, heat transfer, and their application to the manufacture of wrought steel products—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "M.W.2".

LECTURER, ASSISTANT PROFESSOR, POSTDOCTORATE FELLOW, and RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICS—Head of the Department of Physics, University of British Columbia, Vancouver, B.C., Canada.

LECTURER IN MATHEMATICS, to teach pure and applied mathematics to degree standard—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

LECTURERS (with special qualifications in (*a*) organic chemistry or (*b*) physical chemistry) IN CHEMISTRY—The Secretary, Royal College of Science and Technology, Glasgow.

PHYSICIST (with at least an M.Sc. degree or equivalent)—Dr. E. Wilson, Superintendent, General Hospital, St. John's, Newfoundland, Canada.

PHYSICISTS, Experimental Officer or Assistant Experimental Officer grade, to work in collaboration with scientists on research in the following: (*a*) properties of solids under high stress and high rates of strain; (*b*) physics of detonation process and propagation of intense shock waves; (*c*) development of transient spectrographic techniques and application to study of high temperature gas shocks; and (*d*) experimental hydromagnetics—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. C/1463/34.

SCIENTIFIC ASSISTANT (ENTOMOLOGY) to assist in field work on controlling *Culicoides* in Scotland—Dr. D. S. Kettle, Midge Control Unit, Zoology Department, West Mains Road, Edinburgh.

SCIENTIFIC ASSISTANT (with a good science degree, a reading knowledge of two European languages (preferably other than French or German), ability to write good English, and preferably a knowledge of soil science and plant physiology), for work in a scientific information service involving abstracting and indexing—The Director, Commonwealth Bureau of Soils, Rothamsted Experimental Station, Harpenden, Herts.

SENIOR SCIENTIFIC OFFICER or SCIENTIFIC OFFICER CHEMIST (with a first- or second-class honours degree in chemistry or equivalent) IN THE INSECTICIDE SECTION of the Pest Infestation Laboratory, D.S.I.R., Slough, Bucks, for work on contact insecticides for the control of stored-product insects—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.165/8A.

SENIOR TECHNICIAN (with considerable experience in histological and photographic techniques, together with experience in the general work of an anatomy department) IN THE ANATOMY DEPARTMENT—The Secretary, Guy's Hospital Medical School, London Bridge, S.E.1, quoting Ref. STA.

TECHNICIAN (preferably with experience in biochemical or microbiological techniques) to assist in research in the Biochemistry Laboratories—The Secretary, Institute of Dental Surgery (University of London), Eastman Dental Hospital, Gray's Inn Road, London, W.C.1.

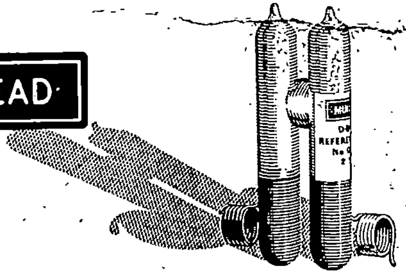
MUIRHEAD



D-845 REFERENCE CELLS

These cells will function under widely varying temperature conditions—be tolerant to a wide range of mounting positions—withstand rough handling and yet maintain an accurate and stable reference voltage. Mounted and unmounted types are available from stock in limited quantities.

SPECIFICATION

E.M.F. 1·0193 volts absolute, subject to manufacturing tolerance of 0·0005 V Unmounted, 0·0002 V. Mounted.

Temperature coefficient Does not exceed 5μV/°C over the range 10°—40° C.

Temperature hysteresis Negligible over the normal temperature range.

Internal resistance at 25° C. Average 800 ohms, maximum 1200 ohms.

Carbon-14 Dated Palæoliths from Borneo.—Tom Harrisson . . 792

RP.35

. . . is a new blue-sensitive recording paper having the excellent photographic characteristics of the well-known 'Kodak' RP.30 paper, plus the advantages of a thinner base and a low-lustre surface.

The thinner base (0.0045″ compared with the 0.0068″ base of RP.30 paper) allows 50% more paper to be loaded into the camera. The paper is rapid-fixing and the thinner base enables the paper to be washed and dried more quickly. The low-lustre surface makes examination and annotation easier.

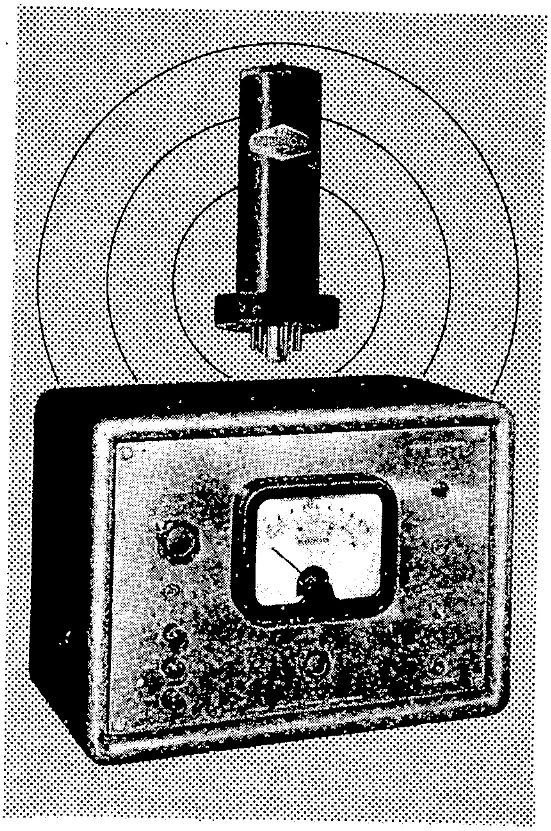
RP.35 paper has been produced to meet the demands of scientists engaged in research on guided missiles and supersonic aircraft. The standards demanded in these fields are, of course, very high. Photographers in other branches of science and industry may therefore find that RP.35 recording paper gives better results than the material they are now using. A short trial would prove the point.

Prices are the same as for RP.30 paper.

Kodak **RP.35 HIGH-SPEED THIN-BASE RECORDING PAPER**

Kodak Limited, Industrial Sales Division, Kodak House, Kingsway, London, W.C.2

'Kodak' is a registered trade-mark



E·I·L

The VIBRON

is a new electronic component, which replaces the electrometer valve in the measurement of very small currents.

The VIBRON is a vibrating condenser unit which, in a suitable circuit, can measure currents as small as 10^{-14} ampere, or resistances as high as 10^{15} ohms, to an accuracy of ±2% and with a zero stability of ±100 microvolts in twenty-four hours. It can be supplied as a unit for building into instruments of your own design, or, alternatively, VIBRON instruments of several types are available from E.I.L.: the Model 33B Electrometer shown here is an example.

Manufactured under British Patent No. 550610 and Patent Application No. 35637/54.

ELECTRONIC INSTRUMENTS LIMITED
RICHMOND SURREY RIChmond 5656

E.8a

THE COMPTROLLERSHIP OF THE PATENT OFFICE

"THAT a scientific office should have a scientific man at its head is a principle which seems obvious but needs to be constantly reasserted, because the administrative officials who influence such appointments are not always sympathetic towards the claims of science." These words are quoted from an editorial published in *Nature* thirty-three years ago, on February 27, 1925. It had become known that the Comptroller-General of the Patent Office was likely to retire and that an administrative officer, without legal or scientific qualifications, had been chosen to fill the vacancy when this should occur.

To-day the importance of applying scientific methods and results to public affairs is so generally accepted in industry and in many other fields that it has become a truism. Nobody would expect Imperial Chemical Industries, or the Atomic Energy Research Establishment at Harwell, or the National Physical Laboratory, to be under the direction of a man who had never worked in a laboratory. But fifty years ago the role of the scientist in administration was merely to supply information or advice to non-scientific administrators, who might or might not be capable of understanding it, and who certainly were ill-qualified to evaluate its significance in relation to policy. Even as late as 1925, however, it was necessary to refer, in the article quoted above, to a "tendency to regard a man of science as a mere adviser who is himself incapable of administrative work. Such an attitude is the more unjustifiable because of the fact that a scientific training is necessarily additional to some degree of education in the humanities, whereas a literary scholar may be quite ignorant of science; so that the former type of upbringing is the more likely to produce the breadth of outlook which is necessary in handling men and affairs". It was to further this point of view that the British Science Guild had been founded, and largely through its work the importance of according the scientist his proper place was acknowledged. Eventually, the British Science Guild, with its assets and functions, was absorbed into the British Association, and the latter began to pay increased attention to the social aspects of science.

But in 1925 the battle had not been won, and a deputation from the British Science Guild, led by Sir Richard Gregory, and including such men as Marconi, Sir Hugo Hirst and the first Lord Melchett, visited the President of the Board of Trade. The daily Press joined in, and after a strenuous battle common sense eventually triumphed. From that date until the beginning of this month, the Comptrollers of the Patent Office have been scientists with legal training and long experience of the intricacies of patent practice.

Meanwhile, the average invention has become immeasurably more technical than before, the rate of filing of complete specifications has increased by half, international negotiations relating to industrial property have become more intricate, the Second World War has left behind a number of problems demanding first-hand knowledge for their solution, and the competition of industry for the services of scientists has increased the need for handling the examining staff with understanding if they are not to be tempted to seek employment elsewhere. Yet successive Comptrollers have contrived to maintain, in the teeth of the most harassing difficulties, the services which the Patent Office renders to industry.

The qualifications needed by the Comptroller of the Patent Office arise partly from the fact that he has to handle a staff which is predominantly scientific and technical, and partly from the nature of the statutory duties laid upon him by the Patents Acts. As regard the first point, "it would be unreasonable", to quote once more from the editorial referred to above, "to subordinate the Examining Staff to the control of a man who is not qualified, by a scientific training similar to theirs, to understand the outlook and mentality with which such a training is associated". That is even more true to-day, for the staff must be able to feel full confidence in its leader if it is to carry out with the necessary zest the gruelling task which it is particularly engaged upon at the present time, namely, that of reducing the long delay in the granting of patents without reducing the quality of the examination, with a consequent increase in litigation.

As regards the Comptroller's statutory duties: his court is a court of first instance for certain classes of patent litigation, and though he delegates some of this work to his immediate subordinates on the examining staff, it has been usual (except in certain instances where bad health intervened) for him to take the most important hearings in person, and in any event to guide his staff on legal points. Comptrollers have also attended international conferences on industrial property in person, and acted as chairman in at least one instance. It is important that they should do so, and that they should be able to deal with the representatives of other countries on a footing of equality in the range of knowledge which comes from a scientific and legal background, with a foreground of experience of the highly specialized subject-matter with which such conferences have to deal.

For the past two years, negotiations have been in progress in relation to patents within the European Free-Trade Area, and they are now entering upon an acute stage. British interests are likely to be at a disadvantage if Germany succeeds in her strenuous efforts to have the Patent Office of the Area established under her tutelage.

We have just stated that the Comptrollers of the Patent Office have had the requisite professional qualifications "until the beginning of this month". It is no secret that the Board of Trade has been faced with a difficult establishment problem in that it has a redundancy of senior administrative officers for whom it has to find suitable posts. Such a post has been provided by the retirement through ill-health of the Comptroller-General of the Patent Office, which by historical accident is a department of the Board of Trade, and an appointment has been made; this has been done by way of surprise, before the action taken in 1925 could be repeated. *Nature* is, of course, in no way concerned with personal considerations; but it is concerned when a vitally important principle, for which it has always fought and which has come to be generally accepted in industry and in government departments of modern origin, has been violated by means of a *fait accompli*. To ask that what has been done should now be undone is to ask a great deal; but, on the other hand, a great deal is owed to the nation by way of reparation by a government department which has acted in such a way at a time when technological progress has become a matter of the utmost urgency in relation to the national interest.

The head of the Patent Office, if he be not a scientist and a lawyer with long experience of patent practice, cannot be more than a figure-head for subordinates who do possess those qualifications, and a figure-head cannot hope to discharge the duties of the office in a way which will give satisfaction. The Patent Office is a vitally important feature of the industrial world, and of international significance particularly at the present time. The appointment of a mere figure-head cannot but do disservice to the national interest.

IONOSPHERIC RESEARCH

Annals of the International Geophysical Year

Vol. 3, Part 1. Pp. xix+168. Vol. 3, Parts 2, 3 and 4. Pp. 169–381. Subscription per volume: 120*s.*; 17 dollars. (London and New York: Pergamon Press, 1957.)

AT this stage in the progress of the International Geophysical Year, which covers the period July 1, 1957, to December 31, 1958, the detailed programmes of observations are well in hand in all parts of the world. The results of these observations are being collected in an internationally agreed form at a number of world data centres, so that they may be available for scientific workers everywhere. Various discussions of these results and their analysis will undoubtedly occur from time to time in the course of normal scientific publications. In order to ensure that a co-ordinated central record of the whole proceedings of the International Geophysical Year is available for both present and future readers and students, it was decided, at an early stage in the discussions of the Special International Committee (C.S.A.G.I.), to publish a connected series of Annals of the International Geophysical Year. These are published by the Pergamon Press, Ltd., under the general editorship of Sir Harold Spencer Jones, assisted by an advisory board comprising international experts in the various disciplines involved.

The first two volumes of the series will deal, respectively, with the history of the events leading up to the present International Geophysical Year, and with the proceedings of the Special International Committee and its associate bodies. Vol. 3 is, however, the first to be published since it was produced originally in the form of a series of radio instruction manuals for those engaged in the study of the ionosphere. With the aid of the component sections of this volume, the detailed technique for sounding the ionosphere and presenting the results has been standardized together with the associated terminology. They are, moreover, much more than booklets of instruction and guidance. In its present published form, this volume forms a notable contribution to the somewhat sparse number of available books dealing with the ionosphere and various other radio phenomena, such as atmospherics, associated with the atmosphere.

Vol. 3 is divided into four parts, of which the first, entitled "Ionospheric Vertical Soundings", has been compiled by J. W. Wright and R. W. Knecht (U.S. National Bureau of Standards) and K. Davies (Radio Physics Laboratory, Ottawa), and edited by W. J. G. Beynon and G. M. Brown (University College of Swansea). An introduction covering the programme of the International Geophysical Year is followed by a chapter dealing with ionospheric physics, outlining the main characteristics of the ionosphere which are studied by radio techniques. There follow short descriptions of the fourteen types of ionosondes at present available; and practical instructions are given for adjusting the equipment to obtain the best results. The next chapter, on "Interpretation of Ionograms", provides detailed guidance on the evaluation of the ionospheric parameters from the photographic records, the great variety of which is illustrated by some fifty excellent photographs. Chapter 6, on "Reduction of Ionograms", is equally helpful and well illustrated, and it should prove invaluable to a newcomer to this complicated technique. A short chapter on the assessment of the quality of the data and a very brief list of references are followed by six appendixes which deal with programmes, interchange of data and suggestions for research at stations.

Part 2 deals with "The Measurement of Ionospheric Absorption" and has been compiled by a number of authors with considerable experience in this field: W. R. Piggott (Radio Research Station, Slough), W. J. G. Beynon and G. M. Brown (University College of Swansea) and C. G. Little (Geophysical Institute, College, Alaska). An account is given of the general theory of the absorption of radio-waves in the ionosphere, and of two methods of measurement; namely, the pulse reflexion method using ionosonde technique, and the other, developed particularly by radio-astronomers, using radio-waves of extra-terrestrial origin. As in the preceding part, the subject of nomenclature and presentation of results is dealt with in appendixes.

The third part is entitled "The Measurement of Ionospheric Drifts" and comprises separate contributions by B. H. Briggs (Cambridge), L. G. H. Huxley (Adelaide) and J. S. Greenhow (Manchester). The separate chapters deal with the measurement of ionospheric drift velocities by simultaneous fading records on three receivers, by observations on meteor reflexions, and by some other techniques available to ionospheric physicists and radio astronomers.

The contents of Part 4 conform with its heading, "Miscellaneous Radio Measurements", but some of these are not immediately obvious as coming under the general title of Vol. 3, "The Ionosphere".

Nevertheless, the six contributions form a very appropriate ancillary part of the volume and are certainly directly related to portions of the programme of the International Geophysical Year under active study at the present time. These individual papers are entitled: "The Measurement of Atmospheric Radio Noise", by F. Horner (Radio Research Station, Slough); "Whistlers and Dawn Chorus", by M. G. Morgan (Dartmouth College, Hanover, U.S.A.); "Radio Reflections from Aurorae", by A. C. B. Lovell (Manchester), P. A. Forsyth (Saskatchewan) and L. Harang (Auroral Observatory, Tromsö); "Apparatus for Radio-Echo Meteor Survey", by A. C. B. Lovell; "Ionospheric Forward Scatter", by K. L. Bowles (U.S. National Bureau of Standards); and "Ionospheric Back Scatter", by A. M. Peterson (Stanford University). All these sections form well-illustrated reviews, each with selected references which should prove useful for further study.

The publication of this volume (in two sections) shows that the work of preparation for the International Geophysical Year has successfully stimulated the production of a most useful addition to the scientific literature on the detailed characteristics of the ionosphere and related physical phenomena.

R. L. Smith-Rose

ÅNGSTRÖM RADIATION AS PHENOMENON AND AS TOOL

Handbuch der Physik

Herausgegeben von S. Flügge. Band 30: Röntgenstrahlen. Pp. vii+384. Band 32: Strukturforschung. Pp. vii+663. (Berlin: Springer-Verlag, 1957.) 88 and 144 D.M., respectively.

These books, though edited, printed and published in Germany, are largely written in English. In Vol. 30 only the first chapter, on the production of X-rays, by W. Schaaffs, is in German. The remaining chapters deal with experimental methods of X-ray spectroscopy at ordinary wave-lengths, by A. E. Sandström; experimental methods of soft X-ray spectroscopy and the valence-band spectra of the light elements, by D. H. Tomboulian; X-ray microscopy, by P. Kirkpatrick and H. H. Pattee; and the continuous X-ray spectrum, by S. T. Stephenson. Vol. 32 contains French contributions also; the chapters are on experimental methods for determining crystal structures by X-rays (in French) by A. Guinier and G. von Eller; on the theoretical principles of structural research by X-rays, by J. Bouman; on the study of the structure of liquids and amorphous substances by means of the diffusion of X-rays (also in French), by G. Fournet; on size of particles and lattice defects, by W. W. Beeman, P. Kaesberg, J. W. Anderegg and M. B. Webb; on electron diffraction (in German), by H. Raether; and lastly on neutron diffraction and interference, by G. R. Ringo. It is the last two chapters that necessitate 'Ångström radiation' instead of 'X-radiation' in the title of this review.

The names of the authors guarantee the quality and accuracy of the various chapters. Vol. 30 contains references up to 1956, but much of it has a curiously old-fashioned ring, as if it could have been written in the thirties without much difference. (The chapters on soft X-ray spectra and X-ray microscopy are clear exceptions.) In the field of emission spectra of medium wave-lengths, however, there are signs of a revival of interest. Sandström, in summing up the experimental results, states "These two effects [asymmetry and overlapping] raise the question of the definition of the wave-length of a line with a finite width. Usually the wave-length of the peak intensity is preferred as it is the one detail most easily identified. However, the centre of gravity of the area below the intensity distribution curve could also be chosen. . . . No X-ray wave-lengths have been determined with an accuracy better than ± 0·002 XU, which value has to be considered the ultimate limit of accuracy, systematic errors excluded. Some narrow lines in the region of medium wave-lengths excepted, the absolute value of the error certainly exceeds ± 0·004 XU. Considering the systematic errors, as well, errors 10 times as big are to be expected". The differences between peak and centre-of-gravity wave-lengths, and systematic errors of 4×10^{-5} A., are big enough to be disturbing in the type of counter diffractometry now being developed, and it is to be hoped that the needs of crystallographers will stimulate the spectroscopists, who are presumably better equipped for the undertaking, to push the systematic error into the next decimal place, and to produce reliable line profiles extending several half-widths on both sides of the peak.

I am a crystallographer, and I turned with some relief from the phenomenon to its applications. Guinier and von Eller's description of experimental techniques is characteristically lucid. Bouman manages to give the theory of almost everything from symmetry elements to intensity statistics, not excluding lattice distortion, in 140 pages. Fournet's chapter on amorphous states and that of Beeman *et al.* on small particles and lattice defects carry particular aspects of the theory considerably further, and supplement the experimental techniques on low-angle scattering. The chapters on diffraction of material particles contain much to fascinate the conventional X-ray worker.

The German and the English sections are indexed in both German and English in the two volumes. The French sections in Vol. 32, however, are indexed only in French, a fact that does not seem to be stated clearly anywhere, and was discovered empirically. There are copious references to the original papers by means of footnotes, and each chapter ends with a general bibliography. The bibliographical coverage seems very thorough; only two papers which I sought were not found mentioned in the expected places. There are no author indexes, so it could not be checked whether they appeared elsewhere. Altogether, these two volumes will be indispensable for the spectroscopist and the crystallographer, and each will learn much from the volume intended for the other.

A. J. C. Wilson

RADIATION PHYSICS IN MEDICINE

Radiological Physics

By M. E. J. Young. Pp. x+365. (London: H. K. Lewis and Co., Ltd., 1957.) 42*s.* net.

Medical practitioners specializing in radiodiagnosis or radiotherapy require an understanding of certain aspects of radiation physics of a relatively advanced nature. There are few suitable text-books on the subject for doctors preparing for their professional examinations, and thus a new work directed to their needs is welcome, particularly when it is as well written and presented as the volume under review. It should, moreover, be of value to a wider circle of readers, including new entrants to the field of medical physics.

After introductory chapters, the production of X-rays including those in the megavoltage region is considered in some detail, and is followed by an account of naturally occurring radioactive sources. There is one chapter on the interaction of X- and γ-rays with matter, while two are devoted mainly to methods of measurement of ionizing radiation but include discussion of the principles of dosimetry. A chapter on the physical principles of diagnostic radiography is followed by an account of the chemical and biological effects of radiation. The therapeutic uses of X- and γ-radiation are covered in some detail with examples of treatment planning. The production and medical applications of artificial radioisotopes are next described, and the final chapter deals with radiation hazards and protection. Each of the main chapters has a list of references and a selection of appropriate examination questions.

In general, the clarity and conciseness of expression are noteworthy, but the value of the book to students would be enhanced by more frequent use of cross-reference. The author has made allowance for differences in the mathematics and physics background of his readers by the use of small print for more advanced explanation, although this practice has not been followed entirely consistently.

Some misprints have been noted, such as the repeated use of 'Ce^{137}' when 'Cs^{137}' is intended and '8 mA' for '3 mA' in the fluoroscopy conditions in Table 9.01. One or two ambiguous or even erroneous statements have been overlooked, for example that X-ray pulses from a betatron have an interval of $\frac{3}{4}$ cycle, and it is unfortunate that the calculation on p. 199 relating to foreign-body localization is incorrect. These criticisms, however, relate to minor defects in a text-book that can be warmly recommended.

G. W. Reed

OCCUPATIONAL DISEASES

The Diseases of Occupations

By Donald Hunter. Second enlarged and revised edition. Pp. xvii+1100+16 plates. (London: English Universities Press, Ltd., 1957.) 105*s*. net.

DR. DONALD HUNTER is one of our most talented medical teachers, and few who have listened to his words can have failed to be impressed by his wide knowledge in the field of occupational medicine.

He has given us the benefit of his knowledge in a remarkable text-book, which, in its first edition, has already become the standard work on this subject in the British Isles. I venture to suggest that it should be read by all consultants, who will find it not only extremely entertaining but also a revelation of the wide variety of ways in which occupation can affect health.

In this second edition, eleven new illustrations have been added, making a total of 447, and certain additions and corrections have been made in the text, but the general layout and arrangement of the sections remain unchanged. The total number of pages is now 1,100 compared with 1,046 in the first edition. There are comprehensive bibliographies at the end of each chapter.

Several additions have been made to the first four chapters concerned with the history of the subject. These include sections on metal workers in Greek, Roman and Teutonic mythology, a description of Alexander Gordon's views on the cause of puerperal fever, the status of the lower middle classes, and the hey-day of the Lancashire cotton industry. There is a most useful and much-needed section on the importance of vital statistics and epidemiology, including the work of Dr. John Snow on cholera. Unfortunately there is no account of the present-day use of morbidity statistics in industry. This is a pity since so much has been done in recent years, particularly by such organizations as the London Transport Executive. A description of the value of this type of work would have been a welcome addition. There is no adequate account of the extremely valuable Occupational Mortality Supplement 1931 and the Supplement for 1951, based on a 1 per cent sample. There is a critical review of the findings of the Sadler Committee to inquire into the working conditions of children in factories. Due credit has now been given to the Perkins family of Leeds and their early discoveries in the dyestuffs industry.

These items are mentioned to indicate the vast field which has been covered in the historical section of the book.

The Factories Act 1948 is discussed, but unfortunately there is no mention of the fact that the examining surgeon is now called the appointed factory doctor.

There are new sections on the National Insurance Industrial Injuries Act, the work of the National Coal Board Medical Services and an excellent description of the workings of the Disabled Persons Employment Act. The value of health education in industry is given its due emphasis. In all the sections on toxicology one marvels at the wide knowledge of industrial processes possessed by the author; the section on lead poisoning is particularly informative and full of fascination even for a lay person. Additional information has been given concerning vanadium poisoning in relation to petroleum and to boiler cleaning. There are a few slight additions to the section on manganese poisoning.

There is a new section on cadmium poisoning in man and in experimental animals. The section on thallium poisoning is completely new. There is an excellent account of hazards in the iron and steel industry and a description of the Iron and Steel Foundries Regulations 1953. The new section on sewer men gives a graphic account of the hazards of this dangerous job and the cheerful disposition of those employed in it.

There is an up-to-date account of a nuclear power station and the dangers associated with it. In the next edition the public-health hazards might be discussed in more detail. In a book which is so comprehensive and which covers such a wide field it is almost inevitable that some minor items should be omitted.

Everyone concerned with the health of workers should have access to this book. Although it is written by a consulting physician primarily for medical men, parts of it could be read with profit and interest by any intelligent layman. I regard the price of £5 5*s*. as reasonable, providing very good value for money.

W. Hobson

ARCTIC AND ANTARCTIC

Arctic Research

The Current Status of Research and Some Immediate Problems in the North American Arctic and Subarctic. Edited by Diana Rowley. (Special publication No. 2 of the Arctic Institute of North America. Reprinted from *Arctic*, Vol. 7, Nos. 3 and 4.) Pp. 261. (Montreal: Arctic Institute of North America, 1955.) 3.50 dollars.

Arctic Frontiers

United States Explorations in the Far North. By Dr. John Edwards Caswell. Pp. xv+232+16 plates. (Norman, Oklahoma: University of Oklahoma Press, 1956.) 3.75 dollars.

Men against the Frozen North

By Ritchie Calder. Pp. 279+15 plates. (London: George Allen and Unwin, Ltd.; Toronto: Thomas Nelson and Sons (Canada), Ltd., 1957.) 16*s.* net.

Spring on an Arctic Island

By Katharine Scherman. Pp. xvi+331+12 plates. (London: Victor Gollancz, Ltd., 1956.) 18*s.* net.

THE higher latitudes, both north and south, in these days receive an amount and style of attention which is not altogether in accord with reality. Vestigial glamour, lack of perspective, research progress, public ignorance and polar beauty, are among the attitudes which characterize, with varying degrees of helpfulness, the arctic literature of to-day. The present four volumes under review are diverse in worth, style, and subject, and all will find grateful readers. But those readers will be distinctly varied in type and taste, some learned, others ignorant but eager to read if the fare is, as some would say, served in the contemporary manner. The first of these four volumes is an important work.

"Arctic Research" is a truly important compilation and reference book. Its twenty-six chapters, each with its list of references, are about equally divided between the physical, the biological and the social sciences. There is a most impressive list of field research projects sponsored by the Arctic Institute since its foundation.

This work was not intended to provide a complete picture of arctic research, not even of North American arctic research, at this date. That would have been a goal impossible of attainment. Rather was the attempt to define the present state of knowledge in a selected variety of fields where individuals of prominence are available to perform the task. The introduction is by the late Dr. R. C. Wallace, the executive director of the Arctic Institute from 1951 until his death in 1955. Dr. Wallace played a great and vigorous part in the continuing growth of this energetic joint Canadian and United States organization. But the brunt of the work, in the production of the volume and the assembling of the authors, is due to Mrs. Diana Rowley, the editor. Her task cannot have been easy: the result is admirable.

The chapters are naturally of varying quality, but in general it is distinctly high. Excessive verbosity, that intellectual disease of North America, has been fairly well controlled, though we are still presented with 'population enumeration' for 'census' and similar word wasters. The lists of references are not overloaded; indeed, in a few instances further references to the scientific literature of Europe might have been helpful.

Photographs are quite properly not numerous. There are four striking pictures of the retreat of the North Dawes glacier in Alaska between 1889 and 1950, a total of 6,500 feet.

This admirable volume may well be compared with "Problems of Polar Research" issued as Special Publication No. 7 of the American Geographical Society in 1928. That earlier work had a long and useful life, and so will "Arctic Research".

"Arctic Frontiers" describes the period of United States arctic explorations from 1850 to Peary's return from the attainment of the North Pole very nearly fifty years ago. As the author says, "This is the narrative, not of isolated adventures, but of a movement". This is an interesting and useful introductory record of what was afoot and when. The reader may well feel that he is perusing the competent précis of an extensive narrative; and that seems indeed to be so, the background work being the same author's study of "The Utilization of the Scientific Reports of the United States Arctic Expeditions 1850–1909".

"Men against the Frozen North" is a successor to the same author's two similarly titled books where our species is set as an adversary of deserts and jungles. This is not the place for detail. The author travelled very widely over the northern parts of the American continent, the Arctic Archipelago and Arctic Ocean. He did so in a very short time, and he is a scientific journalist of enthusiasm, discernment and repute. He knows full well that a large fraction of the population must be tempted to read by devices such as the use of direct speech and minor jokes, and that then information can be inserted like the filling of a sandwich. As *The Times* commented upon the on-stage disrobement of a revue star, "if you like that sort of thing; it is extremely well done".

"Spring on an Arctic Island" is by a woman author who spent six weeks in 1954 on Bylot Island off Northern Baffin Island in 73° north latitude. This is a simple, personal tale, well told by one to whom all was happy novelty. "Above all we got to know some Eskimos." There are some attractive photographs. G. C. L. BERTRAM

POISONOUS PLANTS

The Toxic Plants of Western Australia

By C. A. Gardner and H. W. Bennetts. Pp. xxx+253+52 coloured plates. (Perth: West Australian Newspapers, Ltd., 1956.) £(A)2 10*s.*

THE rich and varied flora of Western Australia, which has so many affinities with the flora of the Cape in South Africa, is noted for the number of highly ornamental or beautiful plants that it contains. Unfortunately, it contains also a large number of species known to be poisonous. These have been the cause of loss and anxiety to stock-owners since the days of the earliest settlers. A great deal of knowledge regarding these harmful plants has been accumulated in recent years, thanks largely to the investigations of the two authors of this book. They have now produced, in a most scholarly fashion, what is the first comprehensive work on the poisonous plants of Western Australia. Both authors are eminent in their respective fields—botanical and veterinary—and together they have formed an ideal partnership for work of this kind. It is to be hoped that the toxic plants in other parts of the world, particularly the less-developed countries, will be similarly dealt with.

The book has purposely been written in a manner that will enable pastoralists and farmers to recognize symptoms of poisoning and to identify the plants that may be responsible. It is well illustrated with coloured plates and line drawings. Each species is treated separately and a detailed description of it provided. This is followed by information on toxicity, symptoms and post-mortem appearances. An appendix lists the toxic plants likely to be found in each of the sixteen districts of Western Australia. Other appendixes give lists of the cyanogenetic plants and those known to cause photosensitivity, dermatitis and hay fever. As quite a number of the species dealt with occur in other parts of the world the book is likely to be of value in other countries.

F. N. Howes

WHEAT IN AUSTRALIA

The Wheat Industry in Australia

By Dr. A. R. Callaghan and Dr. A. J. Millington. Pp. viii+486. (Sydney and London: Angus and Robertson, Ltd., 1956.) 63*s*.

WHEAT is by far the most important crop in Australian agriculture, and next to wool it is the most valuable product. Australian wheat accounts for about 5 per cent of the world output, but its international significance is greater than this figure suggests, because Australia is one of the four major wheat-exporting countries. The history of wheat cultivation in Australia provides an excellent example of agricultural evolution; starting from an exhausting mono-culture on virgin land after clearing and burning the native vegetation, it was improved by the introduction of fallows and fertilizers, especially superphosphate, and more recently by diversified cropping and alternation with leguminous pasture, in an attempt to achieve stability of yield and to prevent soil erosion. The extensive cultivation of wheat with a minimum of man-power was made possible by the invention of special implements and machines adapted to local conditions. These are a few of the reasons that justify the publication of "the first comprehensive account of the Australian wheat industry".

This book is certainly comprehensive. It starts with a history of the establishment of agriculture in Australia, and its development up to the present. Some introductory chapters describe the climate and soils of the wheat lands, and discuss soil structure, plant nutrition and the use of fertilizers in general terms. There are a useful summary of Australian work on the effect of fallow and of leguminous crops on soil nitrogen, and an account of 'dry-farming', the benefits of which are shown to be due to conservation of nitrogen, not water, and to weed control. Variations in husbandry on the different soil types of the wheat belt, and possible future developments in cropping systems are discussed. There is a short general description of the morphological changes during growth of a wheat plant, not specifically related to Australian varieties or conditions. Later chapters deal with the improvement of wheat varieties by selection and breeding, wheat diseases, and the implements and machines used in wheat growing. The rest of the book, about a quarter of it, is concerned with non-agricultural topics, such as storage and marketing of grain, its conversion into flour and bread, and the economics of world trade in wheat. Some of these seem scarcely appropriate for a volume of the "Australian Agricultural and Livestock Series". The most conspicuous omission is the lack of any consideration of the quantitative physiology of growth of wheat plants, and the ecology of wheat crops that form the basis on which the wheat industry is built.

The book is lavishly illustrated with nearly 300 photographs, diagrams and graphs, but many of them have so little relevance to the theme, and others so nearly duplicate each other (for example, Figs. 140, 141 and 154) that they could have been omitted with little loss, and possibly some reduction in cost. It is full of factual information, clearly presented and critically discussed, and generally succeeds in its declared intention of giving "an overall appreciation of the industry and its problems"; but it could have been shorter, more selective, and more readable if the authors had written for a more restricted audience, and had not tried to meet the requirements of "the farmer, the specialist, the student and the general reader" all within the same volume.

D. J. Watson

COMMON LANDS

The Common Lands of Hampshire

By Dr. L. Ellis Tavener. Pp. vii+123+8 plates+7 maps. (Winchester: Hampshire County Council, 1957.) 21*s*.

WHEN the Royal Commission on Common Land began its work two years ago, the lack of accurate information on the status and distribution of common land in England and Wales was at once apparent. The official estimate of about 2,000,000 acres (of which 500,000 may be in Wales) was based on a return made so long ago as 1873, together with some later information on larger areas suitable for war-time reclamation. Only one county, Cambridge, had made a survey of commons as part of its planning survey. To remedy its own position, the Hampshire County Council commissioned Dr. L. E. Tavener, senior lecturer in geography in the University of Southampton, to carry out a factual study of common land in that county—excluding the New Forest, of which adequate details exist.

The county has published his findings in this handsome volume. Whereas he was provided with a provisional list of 90 commons covering 12,000 acres, he actually found at least 133 commons totalling nearly 17,000 acres, not including innumerable village greens of less than five acres which have not been listed.

A tabular analysis and succinct descriptions of commons by administrative areas are accompanied by a chapter on their soils, and a comparison of the maps in the folder shows clearly the close association of commons with coarse, hungry soils of the London and Hampshire Tertiary basins, and the western end of the Weald. Tavener's pioneer study is of far more than local interest. A careful glossary, an attempt to determine what is a common, an indication of sources of information—notably the enclosure awards—combine to make this an indispensable guide to others who, it is hoped, will take up the systematic study in other counties.

L. Dudley Stamp

Guided Missiles in War and Peace

By Nels A. Parson, jun. Pp. xii+161. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1956.) 28*s.* net.

THIS introductory study, by a member of the United States Army Ordnance Corps, attempts to show the impact of guided missiles on military operations and to describe the technical characteristics of the main classes of missile. The subject is treated at a technical level suitable for non-specialists; nevertheless the book gives a useful account of the basic principles of missile propulsion, aerodynamics and guidance, with clear diagrammatic illustrations. There is a strong tendency to advance the guided missile as the solution to almost every military problem of the future, although the need for specially trained man-power to operate and maintain the associated complex equipment is emphasized. Great importance is attached to the use of submarine-launched atomic missiles and to the provision of medium-range ballistic missiles for use by army commanders. Although, at the time the book was written, the speculations it contains on satellites and space travel may have seemed naïve, the last chapter on 'missiles of peace' has a topical ring in the light of recent events.

In general the book is typical of the spate of publications on missiles which have emanated from the United States in the past few years. For the inquiring layman, as for the soldier, sailor or airman, it gives a readable introduction to the subject, with a number of interesting photographs of American missiles and a summary review of the likely tactical and strategic uses of guided missiles.

Non-Stable Stars

Edited by George H. Herbig. (Symposium No. 3 of the International Astronomical Union.) Pp. viii+200. (Cambridge: At the University Press, 1957.) 30*s.* net.

THIS volume contains the talks given at a symposium of the General Assembly of the International Astronomical Union held in 1955 at Dublin. It is concerned mainly with stars which for one reason or another are thought to be unstable, or near instability, especially T Tauri stars, flare stars, novae, Wolf-Rayet stars, and eclipsing binaries.

Among the more interesting contributions are those on T Tauri stars, peculiar objects to which A. H. Joy first directed attention in 1945. They are dwarf stars, irregularly variable, with late-type spectra but showing emission lines, and associated closely with interstellar matter. At first their peculiarities were attributed solely to collision with gas clouds, but the association between stars and gas is now thought to be more than fortuitous. The general opinion is that these stars are young and, indeed, that we may be witnessing some stage in their formation. Another important paper is that by M. F. Walker, giving evidence for extremely rapid light variations in old novae, especially DQ Her, better known perhaps as Nova Herculis 1934. A. McKellar and R. M. Petrie give some valuable measures of spectrum line changes during ingress and egress in 31 Cyg, where a *B*5 star is eclipsed by a super-giant *K* star. The results show irregular structure and movement in the *K* star's atmosphere, giving us a decidedly more complicated picture than is usually contemplated in theory.

Much attention is given to ejection of matter by one component of an eclipsing binary and interception by the other. The opinion appears to be growing that some such mechanism is often operative, with a significant and possibly rapid effect on the evolution of the component stars. Z. Kopal reports some computations, based on a very simple model, to deduce the actual trajectories for gas particles from one star to the other. One may hope to see more work of this kind.

But valuable and interesting though these and other papers in this book may be, I have been left with a rather depressing suspicion that in this subject we have too many complications and too few significant facts, too much hopeful speculation and perhaps not enough hard thinking. We need new measurement techniques, deliberately designed to answer specific questions, and not merely for the purposeless collection of more data with which to confuse ourselves; and we need fresh theoretical ideas, rigorously worked out. If this symposium stimulates such developments it will have justified itself.

R. O. REDMAN

The Origins of Modern Science, 1300–1800

By Prof. H. Butterfield. New edition, revised and enlarged. Pp. x+242. (London: G. Bell and Sons, Ltd., 1957.) 16*s.* net.

IN view of its intrinsic value and the many appreciative reviews of the first edition, including that in *Nature* (165, 333; 1950), it is very fitting that "The Origins of Modern Science", published in 1949 and reprinted in 1950 and 1951, should now appear in a revised and enlarged form. Referring to the lectures which he delivered for the History of Science Committee in Cambridge in 1948, Prof. H. Butterfield writes, "In this revised edition they appear now with some of their original errors removed, some judgments altered, and some changes which reflect the advance of knowledge in the intervening years".

Thus, although this book retains its general plan, its value is enhanced by the author's considered judgment, which finds expression in revision and expansion, here and there, of the various chapters. A summary of the importance of the 'theory of impetus'; an appreciation of the contribution to modern science of fifteenth-century art; a discussion of the notion, brought to a climax in the eighteenth century, of 'the Great Chain of Being', are examples. Not least in value are the suggestions for further reading, which have also been brought up to date.

This new edition is specially welcome in a world which is still in need of the historian's as well as the scientist's point of view.

H. D. ANTHONY

Pioneer of Sociology

The Life and Letters of Patrick Geddes. By Philip Mairet. Pp. xx+226. (London: Lund Humphries and Co., Ltd., 1957.) 21*s.* net.

TO convey a vivid and accurate impression of a personality so dynamic and many-sided as that of Patrick Geddes is no easy task, and though the thirty-odd letters Mr. Mairet allows himself in his two hundred or so pages appear to be well chosen and representative, they are scanty measure for the task. None the less, the book is well balanced and gives a clearer and more continuous picture of Geddes' whole life and work than Mr. Broadman's earlier book. In his final chapter Mr. Mairet attempts a brief but admirable appreciation of the significance of Geddes' work, and it is here in its exposition of the contribution which Geddes' work and thought has made to the problems of to-day that the great merit of this book is to be found. Not simply in town and country planning, in the community centre and in like fields of sociology, but on a host of educational issues such as the multi-racial university (as Sir William Holford notes in his foreword), the functions and work of a university, the fragmentation of knowledge, halls of residence and technical assistance, Geddes had stimulating and sensible ideas, the reference of which in the context of to-day is apparent from Mr. Mairet's exposition. It is the more unfortunate, therefore, that the book is robbed of its full value by the omission to supply those bibliographical details which would enable the reader when interest is aroused to turn to Geddes' own writings and study for himself the implications of his thought. The book is also marred by some careless writing, inaccuracies of description, for example of the Committee of Intellectual Co-operation, and the index is erratic and might well be more complete. R. Brightman

Tree Injuries

Their Causes and Their Prevention. By H. L. Edlin and M. Nimmo. Pp. v+167. (London and New York: Thames and Hudson, Ltd., 1956.) 21*s*. net.

THE post-war boom in horticultural societies has had its parallel in a marked revival of interest in arboriculture, and for this type of reader the book under review can be strongly recommended. It is eminently readable, the information provided is thoroughly reliable and, above all, the 125 photographs provided are fascinating. With the text these should provide a means of recognizing and explaining all the common, and some uncommon, forms of damage and abnormality likely to be seen about the country, and should also serve as a warning of the harm that may be caused inadvertently by man. Some people may find life the duller for the sensible answer given to the perennial question as to what damage is done to a tree by ivy, but they may perhaps find compensation in becoming knowledgeable about many more recondite problems. It may be pedantic to quarrel with the classification of old age, coppicing, spiral grain, etc., as 'injuries', particularly as the book would be much the poorer for their omission, but this leads to a misleading impression that 'prevention', as mentioned in the title, is not very adequately covered. In fact, such measures as are possible for the prevention of diseases and defects are given with commendable brevity and practical sense.

More than seventy types of 'injury' are described, and these are grouped conveniently according to causes, such as climate, man, mammals and birds, insects, climbing and parasitic plants, fungi and old age, with a chapter on deformities and curiosities. A useful bibliography of about forty articles and books is included. L. Chalk

Insect Life in the Tropics

By T. W. Kirkpatrick. Pp. xiv+311. (London and New York: Longmans, Green and Co., Ltd., 1957.) 35*s*. net.

THIS book may reasonably be likened to a small text-book on entomology in which particular point is made of selecting from tropical forms of insect-life examples to illustrate principles in insect biology and behaviour. The author draws largely from his own experiences and observations in East Africa, Trinidad, Egypt and the Sudan. It is written primarily for the layman but contains so much information about different sorts of insects that it is likely to be helpful and of interest to the entomologist curious about insects beyond his speciality. The opening chapter considers briefly the nature of climates in the tropics. Two further chapters deal with the essentials of insect structure (mainly external), with some special reference to sensory organs, and the classification of insects to the level of orders. This is done in sufficient detail to satisfy the layman's aspirations to approach his hobby scientifically. The remainder of the book presents its subject from a biological point of view. Thus, the chapters are on the way insects develop, reproductive mechanisms, food and feeding habits, locomotion, defence and protection, insect social communities and the architecture of insect nests and termitaria. The book is well illustrated with 146 line drawings and photographs, well produced, and of a convenient size for travel.

Heat and Thermodynamics

An Intermediate Textbook for Students of Physics, Chemistry, and Engineering. By Prof. Mark W. Zemansky. Fourth Edition. Pp. xi+484. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 56*s*. 6*d*.

AMONG the present glut of thermodynamical texts, Prof. M. W. Zemansky's book, in a refurbished edition, is still well among the best. It is, the author writes, aimed at physicists, chemists and engineers, but in fact it is most suited to the needs of physicists. It adheres rigidly to the classical approach, eschewing statistical mechanics and quantum theory, although certain facts have to be quoted from these subjects. This restriction does not prevent the author from discussing some of the most recent advances, notably in low-temperature physics. This topic, Zemansky's own speciality, occupies a new and extensive chapter which forms an excellent survey of the field but tends to spoil the balance of the book. Perhaps this will be redressed in a fifth edition with an equally long chapter on the increasingly fashionable problems of high-temperature plasma, undoubtedly of great thermodynamic interest. Ionized gas is studied briefly in the chapter on gas reactions. The concluding chapters on chemical thermodynamics and the phase rule, though very clear, are markedly more theoretical in approach than the physical chapters, which abound in experimental detail. The sections with relevance to engineering are probably the weakest, and the section on heat transfer is necessarily so brief as to be scarcely worth while. A greater emphasis on flow processes is desirable in a thermodynamical text-book for engineers.

The examples at the end of each chapter have been extended and improved. One's only criticism is that many are exercises in mathematics rather than applied physics.

Besides the discussion of low-temperature physics already mentioned, there are several new features in this edition. The faulty Kelvin treatment of the thermocouple has been superseded by the theory of coupled irreversible flows. The relation between information and entropy is touched on with tantalizing brevity. That the book should be so capable of continued development is testimony to the soundness of the original structure.

J. A. Shercliff

THE LONDON PLANETARIUM

By Dr. H. C. KING
Lecturer-in-Charge

H.R.H. the Duke of Edinburgh will be present at the initial lecture or presentation to be held at the new London Planetarium on March 19. After this inauguration the Planetarium will be opening its doors to the general public and offering as many as thirty-five presentations a week, each presentation lasting forty minutes.

The London Planetarium (Fig. 1) is the thirty-third Zeiss planetarium and the first large-scale project of its type in the British Commonwealth. The first was set up in 1924 on the roof of the Zeiss works at Jena, where in eighteen months some 80,000 visitors viewed the artificial heavens. The instrument was thereafter operated at the Deutsches Museum, Munich, and a second projector, later moved to the Haagsche Courant at The Hague, took its place. By 1928 Zeiss had installed twelve planetarium projectors at important sites in Germany and Austria. Rome had one in 1928 and Moscow followed suit in 1929: according to a recent report 20,000,000 visitors have so far visited the Moscow centre project. The first American planetarium, the Adler Planetarium, Chicago, was opened in May 1930. Its success was such that others appeared at Philadelphia (1933), Los Angeles and New York (1935), Pittsburgh (1939) and Chapel Hill, North Carolina (1949). During the 1930's Zeiss planetaria were also built at Stockholm, Milan, Osaka and Tokyo.

The instrument for London is one of a new series made at the Zeiss works at Oberkochen, Western Germany. As such, it is of the type recently assembled in São Paulo and Hamburg. Previously, only the brightest star, Sirius, had been reproduced by a special optical projector; but this system has now been extended and applied to all stars down to those of the second magnitude by the introduction of forty-two special projectors fitted to the main dumb-bell assembly (Fig. 2). Furthermore, the 32 star diapositives, which contain some 8,900 remaining stars and various nebulæ and star clusters, are no longer made of perforated copper foil but are produced by photo-chemical means on scratch-proof plates. New speeds of three and twelve minutes have been introduced into both the diurnal and annual movements, and the Moon projector has been improved to show a brighter Moon with characteristic maculæ.

The building can be likened to a large hollow mushroom having an outer skin of copper-covered concrete, and an inner dome of aluminium alloy. The domes both rest on a circular floor of reinforced concrete 24 in. thick, which in turn is supported by twelve columns. These columns are placed 11 ft. back from the perimeter and act as fulcra so that the mass of the concrete floor inside the circle of columns balances the cantilever plus the weight of the entire dome structure. The thrust downwards to the ground floor amounts to 145 tons per column, and this in turn is taken up by four piles to each column. The piles are 45 ft. long and have their tops 10 ft. below road-level.

The Metropolitan Railway runs along Marylebone Road at approximately 30 ft. from the edge of the building and the crown of the tunnel is some 6 ft. below road-level. Vibration from this source is so heavy that its effects can be heard in the present basement of Madame Tussaud's—some 150 ft. back. Moreover, the direction of the railway changes at the new building and curves away into Baker Street Station; as the trains slow down their wheels lock over to

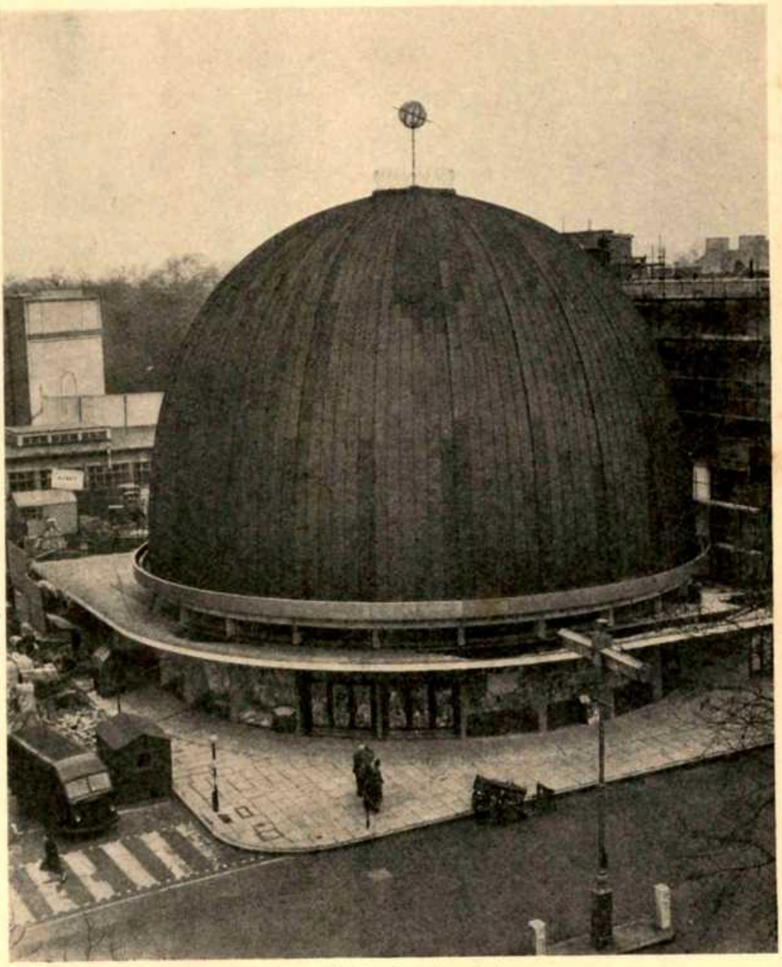


Fig. 1. The London Planetarium

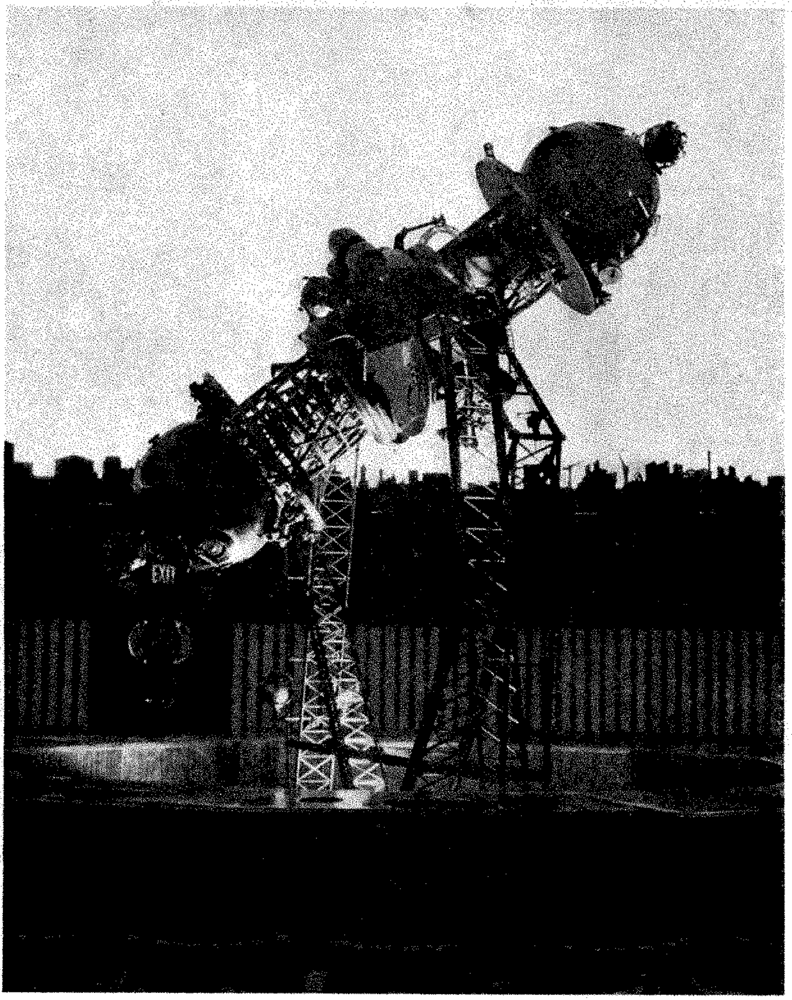

Fig. 2. The Zeiss dumb-bell projector

cause heavy reverberation. It was therefore decided that only weight would overcome ground vibration, and the engineers designed heavy concrete beams on a spider's web pattern. These beams connect up all the pile caps at 10 ft. below road surface and are topped off with an 18-in. thick concrete floor at ground-level. This scheme has proved highly successful. Not only is the floor of the auditorium free from transmitted vibration but also the sound of trains passing beneath is barely perceptible when the auditorium is empty.

In all other planetaria the central projector assembly is permanently mounted at the centre of the auditorium. At London, however, this assembly is carried by a vertical lift mechanism installed by Knight Construction, Ltd. When a lecture is not in progress, the instrument can be seen by the public in the brightly-lit foyer directly beneath the auditorium. In this 'down' position it is protected by a glass cage surround and a large overhead roller-blind. The sequence controls for the operation of the lift, lift blinds and lighting are at the lecturer's console near the northern face of the auditorium.

The auditorium has a seating capacity of 550 and can be given as many as eight changes of air every hour. Good optical projection makes it essential to enforce a 'No Smoking' ban and to filter the greater part of the incoming air. The projection dome, 67 ft. in diameter, is constructed of 16-gauge half-hard aluminium-alloy sheets formed with butt joints and screws to sixteen aluminium ribs. These ribs are held in position by two tubular tension rings and an upper aluminium saucer, and are bolted and insulated to a steel substructure at the bottom. To prevent echoes and reverberation, the sheets are perforated with holes 0·08 in. in diameter at a density of 20 per square inch and backed by a thick blanket of 'Rocksil'. These holes in no way prevent the audience from seeing even the smallest star images.

In most planetaria the blackness of the darkened projection dome can be relieved by a faint blue radiance provided by two special lamps fixed to the top members of the dumb-bell supports. In the London Planetarium this quite realistic auroral glow can be heightened by operating further lights concealed in the dais which surrounds the instrument, and by introducing blue and green 'effects lights' from behind the skyline. The effects lighting is carried out in three rings of cold-cathode tubes in red, green and blue (all concealed behind the plywood cut-out of the London skyline), and is controlled from the lecturer's console. The red lighting is used for special sunrise and sunset effects, and can be faded in or out together with or separate from the blue and green lights.

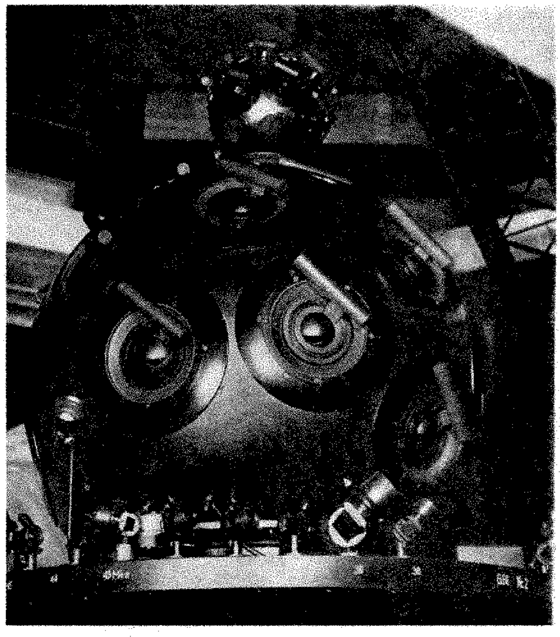

Fig. 3. Southern star globe and small globe for constellation names

Although the London Planetarium is owned by Madame Tussaud's, Ltd., it will operate as a separate entity from the Waxworks Exhibition. So far as the public is concerned, there will be no connexion between the two. It is also the first planetarium to be financed by and operated through private enterprise. As such, its presentations are designed to have the widest popular appeal and are not restricted to special times on just one or two days of the week.

The presentations will be at once entertaining and yet restricted to the facts and findings of astronomy. Each and every aspect of astronomy that the Zeiss equipment can cover will be treated with integrity and in proper context and sequence. The public, as B. J. Bok has remarked, will soon lose interest in presentations of scientific results if the fundamentals of scientific honesty are not strictly observed. School parties will be specially catered for in the morning and early afternoon presentations. Lectures on more advanced aspects of astronomy and courses of lectures on the fundamentals of practical astronomy and astro-navigation will undoubtedly follow in due course. How soon the normal programme can be extended into these most attractive fields will depend largely on the demand. For a year, at least, and until all the necessary technical staff is appointed, the operation of the basic programme with its monthly changes will receive priority.

The Planetarium has its own bookstall, and in addition to souvenir-brochures and booklets will later publish star-guides and low-priced books on elementary astronomy. The foyer will also contain display material arranged to interest the public in the findings of modern astronomy. When the new office block at the rear of the site is completed, the Planetarium will be able to offer an information service on matters astronomical to Press and public alike. It will by then have its own library and reference room, and also the necessary staff to deal with the anticipated heavy correspondence.

THE BRITISH NUCLEAR ENERGY CONFERENCE

SYMPOSIUM ON NUCLEAR ENERGY

SEVERAL chemical engineering aspects of atomic energy were discussed at the British Nuclear Energy Conference Symposium on Nuclear Energy which was held on January 21 in London. The symposium was sponsored by the Institution of Chemical Engineers, and the topics ranged from the problems which are involved when a nuclear power station of the Calder Hall type is started up, to the computation of the performance of solvent extraction columns which are used in purification processes for partially burnt nuclear fuel.

Sir John Cockcroft, as chairman of the Conference, opened the symposium, after which the chair for the morning session was taken by Mr. A. S. White (Atomic Energy Research Establishment, Harwell). Mr. H. G. Davey (United Kingdom Atomic Energy Authority, Windscale) presented the first paper on the "Commissioning and Operation of 'A' Station, Calder Works". Only a short time was available for commissioning the first of the two reactors in 'A' Station, and experimental measurements were restricted to those which would provide essential data. These included making measurements to determine the critical size and to find the optimum number and disposition of control rods required in the fully loaded reactor. These data were substantially supplemented by a more detailed experimental programme during the commissioning of the second reactor.

A cylindrical loading pattern was used, and the critical mass found to be the equivalent of 406 channels as compared with the predicted 475 channels, the difference being almost within the estimated error. A value of $k_{\text{eff.}} = 1{\cdot}0547$ was derived from experimental measurements, compared with the design figure of 1·042. The 48 control rods were calibrated by taking advantage of the closed pressurized cooling circuit to maintain the reactor in a critical condition, by adjusting the air pressure within the pressure vessel.

To ensure successful operation of the plant, it was necessary to test the coolant gas flow-rates through individual fuel channels, the gas leakage, the blowers, the gas circuit and the burst cartridge detection gear. Mr. Davey went on to discuss the work-up to power on August 1, 1956, and the approach to the maximum cartridge temperature of 375° C. on August 27, when the first turbine set was synchronized and loaded up. The second set was commissioned a week later and an electrical load of about 28 MW. was achieved with a reactor heat output of 136 MW. Steady conditions were maintained during September and early October and the official opening by H.M. the Queen was held on October 17, 1956, with the same operating conditions. A deliberate shut-down took place on November 15 and various modifications were made. Afterwards, near design conditions were obtained with an electrical output of 42 MW. at a heat output of 180 MW., with a maximum cartridge temperature of 408° C. The power output was eventually increased to 200 MW. heat in late August 1957. Mr. Davey gave sufficient information to demonstrate that Calder 'A' Station was not difficult to commission and, in fact, most of the teething troubles arose on the more conventional items of equipment.

In his paper on the "Development of the Butex Process for the Industrial Separation of Plutonium from Nuclear Reactor Fuels", Mr. C. M. Nicholls (Harwell) described the work which had been done in the Chalk River Laboratories prior to building the Windscale plant. Development of the Butex (diethylene glycol dibutyl ether) process, which was begun by a chemical team, was continued until proved by pilot-plant operation. The preferred process is one in which the fission products are eliminated by an early stage in a stream which is practically free from dissolved salts. Column studies were carried out, using uranyl nitrate, to study mechanical design details of solvent extraction columns, to provide information on the extraction performance of columns and to check the flow-sheet so far as possible. Some of these studies were repeated, using uranyl nitrate solutions containing trace quantities of plutonium.

The design of the radioactive pilot plant was largely governed by: (*a*) the limitations imposed by the radioactive and toxic nature of the materials handled; (*b*) the novelty of the process; (*c*) the need for versatility in the plant; (*d*) the urgency of the situation; and (*e*) the limited staff and laboratory facilities and restricted space. Mr. Nicholls discussed the effects of these conditions and outlined the form of the plant and flow-sheets. Typical extraction results were given, but it was stressed that the main object of the operations was not to obtain the best overall plant performance but to study the extraction at each stage of the process and to obtain results which could give information for the design of a production plant. The development of production-scale equipment was undertaken by a team from Imperial Chemical Industries, Ltd. The value of the help and consideration given to the United Kingdom team by the Canadians at Chalk River was emphasized by Mr. Nicholls.

In discussing this paper, Mr. Davey described the process development as a remarkable piece of work and emphasized the similarity of both plant and flow-sheets with the present Windscale plant. The salt-free highly radioactive effluent was a feature of great importance, since it enabled the volume of the highly radioactive stream to be reduced 40–50-fold by evaporation before storage. The use of simple types of column had contributed to trouble-free operation, and Mr. Davey said that he was not so enthusiastic about suggested departures to other types of equipment which may lead to more efficient extraction but also to more trouble in operation.

Dr. E. Lofthouse (Imperial Chemical Industries, Widnes), as a member of the Imperial Chemical Industries team which had assisted in the development of the Butex process, pointed out the importance of finding, at Chalk River, that the plutonium extraction was at least as efficient as that of uranium, and this greatly aided the scaling-up work.

"Fission Product Disposal" was discussed by K. Saddington (Windscale). As an inevitable consequence of the operation of nuclear reactors, significant amounts of fission products are formed. The problem of the disposal of unwanted radioactive products will increase with increasing utilization of nuclear power. The problem is finally solved only by complete natural radioactive decay, but this process will take hundreds of years. The alternative methods of tackling the intermediate problem are: (*a*) complete containment (safe storage); and (*b*) dispersion in such a way that, by natural or other causes, the waste is greatly diluted. At Windscale, the highly active waste is concentrated by evaporation prior to storage. Evaporation raises issues of nitric acid removal, and destruction by the addition of formaldehyde may be used as well as steam or vacuum evaporation. The separation of specific fission products from this waste may provide useful radiation sources (cæsium-137 and strontium-90), but the residual solution must still be stored for lengthy periods, since it also contains long-lived alpha-emitting isotopes. Both American and British developments in dealing with highly active effluents were described. They included cation exchange on montmorillonite clays and fused salt calcination.

Medium active liquors may be treated by alumina floc adsorption (as at Windscale) or by alternative coprecipitation processes. After flocculation with alumina, 92–95 per cent of the total β–γ activity and 98 per cent of the trace plutonium are removed. The filtrate is monitored and discharged to sea. American practices include direct ground disposal using the ion-exchange properties of the latter. The small geographical area and dense population of Great Britain probably exclude such methods in this country. Low-active effluent may be discharged directly, or discharge may follow chemical pretreatment. The problem is the same in all cases, to discharge the liquors at such a rate and to a pattern which is defined so as to safeguard the public health and convenience in the widest sense.

Dr. E. Glueckauf (Harwell) discussed alternative methods of nitric acid destruction or removal such as electro-deionization methods. He described work being done at Harwell to fix fission products in the form of insoluble glasses from which the activity could not be released. Mr. Grover (Harwell) mentioned that pilot-plant work was being done in the Chemical Engineering Division at Harwell to convert fission products to glasses.

Sir Hugh Beaver was chairman of the afternoon session. The first paper, on "Nuclear Criticality in Chemical Plants", was preceded by a film entitled "Criticality". This described aspects of process plant criticality in terms which could be understood by plant personnel having little scientific training. Dr. A. H. Gillieson (United Kingdom Atomic Energy Authority, Risley) then presented the paper by himself and Mr. Nicholls. A criticality accident with fissile materials could lead to hazards to plant operators and damage to the plant. Dr. Gillieson briefly reviewed the relevant neutron physics and discussed methods for the safe design of geometrically simple, isolated solution systems. This can be achieved by limitation of the mass, volume or concentration of fissile material in solution or, preferably, by selection of the shape of plant. Geometrically complex systems and the influence on safety of choice of process and plant operation were briefly discussed.

A welcome speaker was Monsieur R. Galley (Commissariat à l'Energie Atomique, Paris), who read his paper on the "Marcoule Plutonium Plant". M. Galley gave a well-illustrated account of the plant, which is based on a tributyl phosphate extraction process. He included interesting details of plant construction, operation, analytical facilities and control, and allied problems of effluent disposal, etc.

"Fuel Processing in Homogeneous Aqueous Reactors", by Mr. I. Wells (Harwell) and Dr. E. Lofthouse, was presented by Mr. Wells. He summarized the relevant features of this type of reactor and discussed the special processing problems involved. It is necessary to keep to a minimum the wasteful absorption of neutrons in order that more fissile material is produced than is burnt (that is, for 'breeding' to be possible). This, and the need for chemical and radiation stability, limits the number of chemical compounds suitable as fissile and fertile materials. Mr. Wells described gas–liquid processing to remove volatile fission products, and solid–liquid separations by cyclones to remove precipitated fission product compounds. Alternative methods of chemical processing include solvent extraction and uranium peroxide precipitation. Mr. Wells concluded that it will be some time before such reactors are applied commercially, since many problems still have to be overcome, for example, the containment of fluids, the handling of slurries and the maintenance of equipment in high-radiation fields.

The final paper in the symposium, on the "Computation of the Performance of a Multicomponent Solvent Extraction System" by Dr. J. T. Wood (Risley) and Mr. J. A. Williams (Windscale), was read by Mr. Williams. He showed how established methods of graphical calculation for immiscible phases may be applied to a complex multicomponent solvent extraction system such as the first extractor of a tributyl phosphate process for irradiated uranium. Partition coefficients for the main components were presented and Mr. Williams demonstrated their use in the calculation of extractor performance. Typical results were illustrated, and the choice of operating conditions, as determined by the behaviour of individual components, was discussed. In conclusion, Mr. Williams pointed out that while the broad outlines of a process can be calculated by the means described it must be emphasized that a reliable prediction of performance can only be made when all the partition data required are available. In some cases (for example, plutonium and ruthenium) it may be necessary to consider kinetic as well as partition effects, and it is more satisfactory to obtain detailed knowledge by experiment under conditions closely approximating, with respect to time of residence and flow ratios, to those of the plant.

F. S. Martin

RUDOLF DIESEL, 1858-1913

By E. J. HOLMGREN

At present the world is passing through a great phase of scientific discovery that commenced with the end of the Second World War. Mankind has seen such periodic surges of scientific achievement before, at which times remarkable discoveries and developments take place that have profound effects upon the subsequent achievements of man. Just such an upsurge occurred in the closing decades of the nineteenth century and the opening years of the twentieth—years which we associate with such names as Parsons, Nobel, Edison, Fleming and many others. It was an age of great scientific pride and perhaps one of the most notable advances (and certainly one that has in recent years seen spectacular changes) was the advent of the compression-ignition engine as a prime mover with its notable promoter, Rudolf Diesel.

Diesel was born in Paris on March 18, 1858, of Bavarian parents. He spent most of his early years in that city, but on the outbreak of the Franco-Prussian War his family's fortunes were ruined and he was sent to England to school in 1870. Later that year he was sent to Augsburg, where he studied at the Technical School, and in 1880 he graduated from the Technical University with record marks. His one ambition was to become an engineer, and after graduating he worked for Prof. von Linde on the development of machinery for liquefying air.

This was the era in which the reciprocating steam engine reached its greatest development ; the steam turbine had yet to appear. Diesel, however, as he worked both in the university and with von Linde, was not satisfied with the steam engine. Not only was it inefficient but also the cost per unit of power was much higher for the smaller than for the larger engines, so that it was an economical proposition only in the larger units.

During his undergraduate years Diesel had first become interested in the Carnot cycle of the theoretically perfect steam engine. He realized that this cycle must be applied in some way to provide a prime mover which did away with the faults of the steam engine. At first he designed an engine to run on ammonia gas in a manner similar to that of the steam engine, but while this was not satisfactory, mainly because of leakage of the gas, it demonstrated that a small economical engine was a possibility.

As a result of his experiments with the ammonia engine, Diesel came to four conclusions : (1) the idea of an engine on the pattern of a steam engine had to be discarded ; (2) combustion of the fuel must be in the cylinder of the engine and not in a boiler ; (3) air must be used as a working medium instead of steam ; (4) high compression is necessary in order that the Carnot cycle be realized. It should be noted in passing that the concept of the compression-ignition engine was not new. In 1896 Charles Arkroyd Stuart had taken out his first patent, and had conceived the idea of fuel injection with compressed air, using a hot bulb as the means of ignition. Diesel dispensed with the hot bulb altogether. Later, Arkroyd Stuart applied for a patent covering automatic injection.

Prior to this time gas engines working on the four-stroke Otto cycle were the only internal combustion engines, and they all employed low compression ratios. With Diesel's engine, high compression was to be a necessity : it was to produce heat so that when the fuel (at first powdered coal was envisaged) was introduced, combustion would take place ; this could be controlled. No air–oil mixture could be introduced or a premature explosion would result.

In 1893, with financial backing from Krupp's and the Augsburg–Nuremburg Engine Works, Diesel constructed his first engine. This was a single-cylinder machine with an external crosshead, working on the four-stroke cycle. The cylinder was not water-jacketed. The engine was driven by external power and when the fuel oil was introduced there was an explosion and the indicator was shattered. The engine, though a failure, served to demonstrate that compression could ignite fuel oil. In a second engine, Diesel introduced certain modifications such as a higher cam-shaft and a water-cooled cylinder jacket. This engine ran for only a minute. The third and fourth engines, built in 1897 and 1898, respectively, were more successful : the latter, although it was only a single-cylinder machine, developed 20–25 h.p.

The success of these experiments, which had been carried on at the Augsburg Engine Works since 1894, with the subsequent triumph of the engine as a workable machine, caused a world-wide sensation. Diesel engines began to be constructed in all parts of the world under licence, for Diesel himself still possessed the patents. Unfortunately, at the turn of the century a number of minor mishaps on one or two machines caused Diesel considerable embarrassment and some financial reverse, during which he sold many of his patents; only later did he realize his mistake.

After 1901 a number of refinements were introduced. Machines of several cylinders were built; trunk pistons were introduced. The four-stroke cycle remained supreme and the oil was injected with the aid of compressed air, that is to say, a mixture of oil and air was introduced at the top of the compression stroke, for which purpose the engine had to be equipped with an air pump. Diesel himself saw the advantages of airless injection, and also of the two-stroke cycle which was peculiarly suitable for his engine. Its advent was delayed for two decades following his initial success because no manufacturer could build a workable fuel-injection pump capable of withstanding the high pressures involved. It was airless injection that made possible the success of the Diesel engine as we know it to-day, particularly in respect to the smaller sizes. Ironically enough, the small-size Diesel engine was not realized as quickly as Diesel had hoped, partly because of the introduction and success of the electric motor.

In 1912, Diesel visited the United States and addressed the American Society of Mechanical Engineers. At this time he was broken both in health and financially, and his death a year later, although mysterious, is generally attributed to suicide.

Diesel's invention can be regarded as comparable in importance to that of the steam engine. It is interesting to note that Diesel foresaw that his engine would eventually change the railways. However, at the time of its introduction the steam locomotive reigned supreme and another twenty-five years had to pass before the railways took any serious interest in Diesel locomotives. Diesel visualized his engine driving locomotives through a mechanical drive rather than through the intermediary of an electric generator and motor. Mechanical transmission was to come into its own, however, in rail cars and small switching engines.

The story of the Diesel engine in construction equipment, marine applications and road transport is well known. The success of the Diesel engine in the First World War in submarines and in the marine world in general gave it an assured place as a prime mover. In road transport, it is interesting to note that Diesel himself designed a road truck but later withdrew it. The early success of the petrol engine in Canada and the United States overshadowed the smaller Diesel engine, which, however, achieved some popularity in Europe. In Germany and Britain Diesel aero-engines made their appearance before the Second World War and were very successful, but gave way to the gas turbine when it appeared.

PROGRESS OF SPUTNIK 2 (1957β)

By D. G. KING-HELE

Royal Aircraft Establishment, Farnborough

SPUTNIK 2 has now been circling the Earth for more than four months, and sufficient observations have been received and analysed to allow a preliminary report on its progress to be made.

Fig. 1 shows how its period of revolution has altered during this time. A marked change in the slope of the curve is apparent between December 20 and January 5, and there are several smaller fluctuations in slope, which are not visible on the scale of Fig. 1. Until mid-December the rate of decrease of period remained fairly constant at about 3·0 sec. a day. There followed a sharp rise to about 4·0 sec. a day in early January. During January the rate fluctuated between 4·4 and 3·9 sec. a day; then in

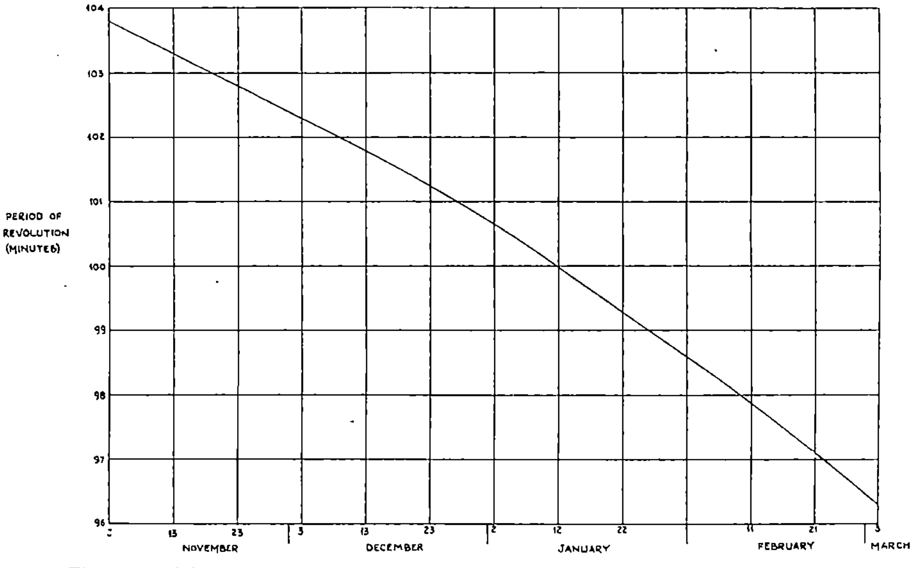

Fig. 1. Variation of the (nodal) period of Sputnik 2 between November 1957 and March 1958

Table 1. Orbital Data for Sputnik 2

Date	November 9, 1957	December 3, 1957	January 22, 1958	March 2, 1958
Time, G.M.T.	05.23 hr.	07.28 hr.	19.23 hr.	16.00 hr.
Orbital period (min.)	103·49 ± 0·05	102·289 ± 0·001	99·206 ± 0·001	96·33 ± 0·01
Semi-major axis (nautical miles)	3,940·2 ± 1·3	3,909·72 ± 0·06	3,830·77 ± 0·06	3,756·5 ± 0·3
Eccentricity	0·0973 ± 0·0004	0·0904 ± 0·0003	0·0728 ± 0·0005	0·055*
Angle from apex to perigee	– 33° ± 1°	– 41·9° ± 0·2°	– 63·19° ± 0·06°	– 83°*

Inclination of orbital plane to equator: 65·29° ± 0·03°.

The rate of rotation of the orbital plane about the Earth's axis was 2·69 ± 0·01 degrees/day at 00.00 hr. on December 1, 1957, and 2·88 ± 0·01 degrees/day at 00.00 hr. on January 20, 1958.

* Accuracy uncertain.

February there was a further rise, from 3·9 to more than 5 sec. a day, followed by a fall to about 4·5 sec. a day. These fluctuations are believed to be genuine and not due to observational error. They imply fluctuations in the effective drag on the satellite, and their interpretation should provide much scope for ingenuity. There have also been striking fluctuations in the apparent brightness of the satellite, often with a period of the order of one minute, and these have generally been attributed to its rotation.

The fluctuations in drag have made it difficult to predict the movements of the satellite accurately, and any estimates of life-time are subject to considerable error. At present the most likely date for the final descent through the atmosphere appears to be April 15; but if the drag were to change abruptly by 20 per cent, as it has done in the past, this date could be in error by up to 10 days.

When Sputnik 2 began its career the orbit had an eccentricity of about 0·1 and the height varied between a minimum of 120 nautical miles and a maximum of 900 nautical miles (1 nautical mile = 6,080 ft.). The satellite was at perigee when going north at a latitude of about 51° N. By the beginning of March 1958, the eccentricity had fallen to about 0·056 and the height varied between 110 and 530 nautical miles. Meanwhile perigee shifted slowly backwards along the orbit, and by the beginning of March had nearly reached the equator. The inclination of the orbital plane to the equator has remained virtually constant, as was expected from theory.

Fig. 1 and the orbital data given in Table 1 are derived partly from the many independent observations on which the prediction service for Sputnik 2 relies, and partly from observations made by kinetheodolite stations of the Royal Aircraft Establishment. I would like to thank all those concerned in the observations and analysis for the help they have given, often in the dark hours before dawn.

NEWS and VIEWS

Royal Society of Edinburgh: New Fellows

At the ordinary meeting of the Royal Society of Edinburgh, held on March 3, the following were elected Fellows of the Society: Prof. H. A. Brück, Astronomer Royal for Scotland and professor of astronomy in the University of Edinburgh; Dr. W. K. Burton, lecturer in natural philosophy, University of Glasgow; Mr. W. McL. Dewar, headmaster, George Heriot's School, Edinburgh; Mr. W. E. J. Farvis, head of the Postgraduate School in Electronics and Radio and senior lecturer, Department of Engineering, University of Edinburgh; Dr. D. Finlayson, research superintendent, British Celanese, Ltd.; Dr. A. R. Hill, lecturer in agricultural zoology, University of Glasgow; Dr. D. K. McE. Kevan, lecturer in agricultural zoology and head of the zoology section, School of Agriculture, University of Nottingham, recently appointed to the chair of entomology, McGill University; Dr. I. R. W. Lominski, senior lecturer in bacteriology, University of Glasgow; Dr. A. McDiarmid, principal scientific officer (veterinary science), Agricultural Research Council Field Station; Dr. Sheila Macintyre, lecturer in mathematics, University of Aberdeen; Prof. D. McKie, professor in the history and philosophy of science in the University of London; Mr. J. P. Maule, director, Commonwealth Bureau of Animal Breeding and Genetics; Dr. A. Meiklejohn, senior lecturer in industrial health in the University of Glasgow; Prof. R. Meredith, professor of textile technology, Royal College of Science and Technology, Glasgow; Dr. Mary J. McD. Noble, principal scientific officer (plant pathologist), Department of Agriculture for Scotland; Dr. D. V. Osborne, lecturer in natural philosophy, University of St. Andrews; Dr. R. Osborne, principal scientific officer, Poultry Research Centre, Agricultural Research Council; Dr. R. V. Rajam, director, Department of Venereal Diseases, Government General Hospital, Madras; Prof. R. A. Raphael, regius professor of chemistry in the University of Glasgow; Prof. I. N. Sneddon, Simson professor of mathematics in the University of Glasgow; Prof. F. S. Spring, Freeland professor in the Royal College of Science and Technology, Glasgow; Mr. J. N. Toothill, general manager, Ferranti, Ltd., Edinburgh; Dr. C. D. Waterston, assistant keeper in charge of the Department of Geology, Royal Scottish Museum; Prof. A. Williams, professor of geology in The Queen's University, Belfast; Prof. M. F. A. Woodruff, professor of surgical science, University of Edinburgh.

NATO Science Committee

The following national representatives on the North Atlantic Treaty Organization Science Committee have recently been nominated: Prof. C. Alexopoulos (Greece); Prof. F. Giordani, professor of general chemistry in the University of Naples (Italy); Prof. R. F. Mayer, vice-rector of Lisbon Technical University (Portugal); Prof. I. I. Rabi, professor of physics in Columbia University (United States); Prof. P. B. Rehberg, University of Copenhagen (Denmark); Prof. S. Rosseland, professor of astrophysics in the University of Oslo (Norway); Prof. A. Rucker, rector of the Munich Technical High School (Germany); Prof. S. J. Sizoo, professor of chemistry in the University of Amsterdam (Holland); Sir Solly Zuckerman, Sands Cox professor of anatomy in the University of Birmingham (United Kingdom); Dr. E. W. R. Steacie, president of the National Research Council of Canada (Canada).

Astronomy at Cambridge: Sir Harold Jeffreys, F.R.S.

Sir Harold Jeffreys, who is to retire from the Plumian professorship of astronomy and experimental philosophy in the University of Cambridge in October, is best known for his work on physics of the Earth and in particular for his discussion of seismological observations and the deduction of the times of travel for earthquake waves. While this work on earthquakes was for many years the centre of his interest, there is scarcely any branch of science connected with the physics of the Earth to which he has not contributed, his work on its thermal history, on stresses in the crust and on tidal friction being particularly well known. The three editions of his book, "The Earth", have for thirty years been the best-known exposition of the application of physics and mathematics to our planet. In the course of his work on earthquake waves, Jeffreys met severe statistical difficulties arising from the failure of the observations to conform to the Gaussian law of errors. This led him to make an extensive study of the basis of the theory of probability and to write a stimulating and entertaining book on the subject. As was to be expected, this led to a vigorous controversy with the guardians of statistical orthodoxy. Jeffreys has also written several books on mathematical topics, including the widely known "Mathematical Methods", which is a joint work with Lady Jeffreys. Since he was appointed to the Plumian professorship in 1946, Jeffreys has devoted his attention mainly to the relation between the Earth's internal structure and astronomical quantities; in particular, he has studied the effect of the Earth's fluid core on nutation.

Prof. F. Hoyle, F.R.S.

Mr. Fred Hoyle, who has been elected to succeed Sir Harold Jeffreys as Plumian professor of astronomy and experimental philosophy, is well known through his many substantial contributions to modern theoretical astrophysics. After an early start in quantum theory, Mr. Hoyle, in collaboration with Dr. R. A. Lyttleton, began to turn his attention to theoretical astrophysics shortly before the Second World War. His outstanding gift of physical intuition has enabled him to appreciate the vital factors in astrophysical situations that are far from terrestrial experience. In this way he has been able to make far-reaching contributions to the theories of stellar structure and evolution, of galactic evolution, of star formation, and of cosmology. Mr. Hoyle has kept in close contact with the outstanding observational astronomers who are associated with the Mount Wilson and Palomar Observatories, and has spent a good deal of his time with them in Pasadena. In this way his theoretical work is backed by an up-to-the-minute knowledge of the latest observational results. The great depth of his understanding has made Mr. Hoyle an outstanding popular writer and broadcaster on astronomical and other topics. He has in the past added great distinction to astronomy in Cambridge as Fellow of St. John's College and lecturer in mathematics, and will continue to do so now in his professorial position.

U.S. National Astronomical Observatory: Dr. A. B. Meinel

Dr. Aden B. Meinel has been appointed director of the proposed new U.S. National Astronomical Observatory by the National Science Foundation in conjunction with the Association of Universities for Research in Astronomy, Inc., which is under contract to the Foundation for the establishment and operation of the observatory at a site to be selected in Arizona (see *Nature* of January 25, p. 236). Dr. Meinel received his Ph.D. in astronomy from the University of California in 1949. He joined the Department of Astrophysics of the University of Chicago in 1950, where he was appointed associate professor. In 1953 he was made associate director of the Yerkes and McDonald Observatories. Dr. Meinel's published work, in addition to optical design, spectroscopy of night airglow and aurora borealis, has included the identification of new band systems in the spectra of OH and N_2, detection of extraterrestrial protons in the aurora, and reproduction of the auroral spectrum in the laboratory by the use of accelerated particles. He has received the Lomb Prize of the Optical Society of America and the Helen Warner award of the American Astronomical Society in 1954.

Dr. Meinel has been associated with the project for the new observatory almost since its inception. He has served as full-time executive secretary to the *ad hoc* advisory panel of astronomers set up to make recommendations on a suitable site. Early in the spring of 1955 he began field work for the selection of possible sites in the south-western area. Assisted by H. A. Abt, Dr. Meinel made a comprehensive examination of the entire region bounded by the Rio Grande on the east, by latitude 36° on the north, and the geographical limits of the United States on the south and west. All available high-altitude rocket photographs were carefully examined. The two scientists flew thousands of miles in a small plane and travelled great distances by car in the course of examining every possible site. Dr. Meinel will continue to direct work on the new observatory from his present field office in Phoenix, Arizona, until a site has been selected.

Social Medicine at Aberdeen: Prof. E. M. Backett

Dr. E. Maurice Backett, who has recently been appointed professor of social medicine in the University of Aberdeen, is forty-two. He graduated in medicine at the Westminster Hospital (University of London) and holds an honours degree in psychology, a diploma in public health, and is a member of the Royal College of Physicians. During the Second World War he served in the R.A.F. (Science Branch). After qualification, he became a Nuffield Fellow in Social Medicine and carried out some work for the Medical Research Council. He was appointed a lecturer in The Queen's University, Belfast, and a senior lecturer at Guy's Hospital Medical School and the London School of Hygiene and Tropical Medicine, jointly. In this post he has been able to develop his interests in undergraduate teaching and also to carry out various investigations, especially in the organization of medical services; quality of medical care; morbidity studies in general practice; social factors in the distribution of polio virus; medical care of deaf mutes; epidemiology of road accidents; and coronary disease in doctors.

Graham Kerr Memorial

A committee has been formed to promote a fund for a memorial to the late Sir John Graham Kerr, who occupied the regius chair of zoology in the University of Glasgow from 1902 until 1935. Lord Boyd Orr, chancellor of the University, has agreed to preside over the committee composed of the following friends and colleagues: Viscountess Davidson, Dr. Muriel Robertson, Sister Monica Taylor, Dr. G. S. Carter, Dr. H. B. Cott, Sir James Gray, Dr. Edward Hindle, Dr. R. A. Staig and Prof. C. M. Yonge. The form of the memorial will depend on the amount collected; but it is hoped that it will provide for the erection of a plaque and the endowment of an annual prize in zoology. Contributions should be sent as soon as possible to the Hon. Secretary and Treasurer, Miss A. E. Miller, Department of Zoology, The University, Glasgow, W.2.

Sir William Siemens Exhibition

A small exhibition presenting the life and work of Sir William Siemens was opened at the Science Museum, South Kensington, on March 10. Prepared in collaboration with Siemens Edison Swan, Ltd., it is based upon exhibits collected together for display at the Central Hall, Westminster, on the occasion of the Siemens Bros. Centenary Lecture on March 5. Charles William Siemens was an outstanding figure in the industrial development of the nineteenth century, combining scientific insight and technical ability with an unusual degree of commercial acumen. He was an acknowledged pioneer of the electrical industry, both on the telegraph and supply sides; and his application of his regenerative furnace to metallurgy made him a leader also of the steel-manufacturing industry The exhibition traces his career and achievements in a chronological sequence. The early years, up to his election to the Royal Society, are represented by exhibits relating to his inventions during that period, and to the beginnings of his work with submarine cables. His later work is represented by exhibits dealing with the practice of steel manufacture and with the development of the electrical industry, including his work on the self-excited generator.

Directory of Societies for Natural History and Cognate Studies

The Council of the British Association for the Advancement of Science has decided, at the invitation and with the financial assistance of the Carnegie United Kingdom Trust, to undertake the publication of a new edition of the "Directory of Natural History Societies", which was first published in 1948 by the Amateur Entomologists' Society. The "Directory" will cover archæological, astronomical, biological, botanical, geographical, geological, meteorological and zoological societies—both national and local amateur bodies—and any other cognate societies which the Advisory Committee may feel should be included. More than three thousand questionnaires have so far been distributed, and it is hoped that any clubs or societies coming within the above terms of reference that have not yet received one will write to the editor, Dr. Averil Lysaght, c/o Bird Room, British Museum (Natural History), Cromwell Road, London, S.W.7.

Scientific and Technical Man-power in Britain

Mr. H. Nicholls, Parliamentary Secretary to the Ministry of Works, replied on behalf of the Lord President of the Council to questions in the House of Commons on February 25 on the sections on research and development in the annual report for 1956–57 of the Advisory Council for Scientific Policy. He said that the Government is playing its part by approving the expansion programme for universities and technical colleges. It is for industry to take full advantage of the skill made available for civil research by the limitation of the defence programme. The Advisory Council is now studying in greater detail the methods of financing research at universities, including the provision of supporting staff. There is no sign at all of serious redundancy. Professional scientific and engineering institutions have offered to co-operate with the Committee on Scientific Man-power in carrying out an annual review of their membership, and in addition it has now been decided to undertake, towards the end of 1958, a further survey of the number of scientists and engineers in Great Britain, similar in scope to that made in 1955. He did not think there is anything to substantiate the suggestion that industry does not keep in close touch with new research in Britain and elsewhere.

Smoke Abatement

Mr. H. Nicholls, Parliamentary Secretary to the Ministry of Works, replying on behalf of the Lord President of the Council to a question in the House of Commons on March 4 regarding research on the measurement and reduction of smoke from industrial chimneys, said that the Fuel Research Station of the Department of Scientific and Industrial Research had developed two types of instrument to simplify the measurement of smoke. One is intended to show a stoker in the boiler house, and the other a smoke inspector outside, when smoke darker than the legal limit is being produced. The Research Station has also developed smoke-eliminating devices for industrial hand-fired boilers, adoption of which would offer a saving of more than 1 million tons of coal a year.

Emergency Supplies of Water

In moving the second reading of the Water Bill in the House of Lords on February 27, the Minister without Portfolio, Lord Mancroft, said that the measure, which was designed to give permanent powers for maintaining public water supplies in serious droughts, would enable us to dispense with Defence Regulation 50*A*, under which orders had been made allowing water undertakings to draw water from emergency sources, and Defence Regulation 56, which had been used to relax restrictions and obligations resting on water undertakings. In the past few years a dozen or more water undertakings have been amalgamated and other discussions are proceeding. Although there are still nearly 1,000 such undertakings, he did not agree that nationalization is the best way to make them efficient; nearly 700 are actively considering amalgamation or re-grouping, and more than £240 million had been spent since the War on water supplies in Britain. Lord Mancroft said that the Bill broadly followed the lines of the Water Supplies (Emergency Shortage Orders) Act of 1934, Clause 1 allowing the Minister of Housing and Local Government or the Secretary of State for Scotland, if either is satisfied that a shortage of water supplies exists or is threatened because of an exceptional drought, to make orders authorizing undertakings to draw water from a source not normally used and to vary restrictions or obligations resting on the undertakings as to the amount of water that may be pumped from a river or the amount of compensating water to be discharged from their reservoirs. The Ministers are required to consider the interests of all concerned with the conservation or use of the water for agriculture, fisheries, industry, navigation, etc. Comparatively little potable water is used by the Atomic Energy Authority.

Committee for Biological Acoustics

In 1956 an International Committee for Biological Acoustics was set up at a conference in the United States to act as a focus for research on human and animal acoustics. The growing interest in this field in Great Britain has created a demand for a national committee, which has now come into being. Its constitution is as follows: *Chairman*, Prof. R. J. Pumphrey, Department of Zoology, University of Liverpool (who is also the British representative on the International Committee); *Secretary*, Dr. P. T. Haskell, Anti-Locust Research Centre, London; *Members*, Dr. E. C. Cherry, Department of Electrical Engineering, and Mr. D. Leston, Department of Zoology, Imperial College of Science and Technology, London; Dr. F. C. Fraser, Department of Zoology and Dr. D. R. Ragge, Department of Entomology, British Museum (Natural History); Dr. L. Harrison-Matthews, Zoological Society of London; Dr. J. W. S. Pringle, and Dr. W. H. Thorpe, Department of Zoology, University of Cambridge.

The committee hopes to arrange meetings on biological acoustics in collaboration with established biological societies, will maintain close liaison with the International Committee, and is also investigating the possibility of setting up a British collection of recorded animal sounds. A necessary first step will be to ascertain the present extent of interest in and the range of research on biological acoustics in Britain, and it is proposed to compile a list of all those interested in the field. Anyone interested in any aspect of human or animal acoustics should send his name and address, with brief comments on his research and field of interest, to Dr. P. T. Haskell, Anti-Locust Research Centre, 1 Princes Gate, London, S.W.7.

The Egyptian Journal of Geology

In these days when the output of scientific literature challenges the ability of the worker in even the most specialized fields to keep himself informed about current research, news of the publication of yet another scientific journal must sometimes be received with mixed feelings. This will not, however, prevent geologists from wishing success to the Geological Society of Egypt, which in 1957 published the first number of the *Egyptian Journal of Geology*, which is to be produced in future twice-yearly. Egypt is a country of considerable mineral wealth and with many features of geological interest; the new *Journal* will provide a useful forum for her geologists, and it is good that the results of their work should be made readily available to the scientific world at large. In the current issue, three of the four articles are concerned with specifically Egyptian problems of stratigraphy, micropalæontology, and mineral resources; the fourth deals with the more general subject of the serial character of igneous rocks. The articles are printed in English with Arabic summaries in this issue, but the editors invite contributions written in any language employing Latin or Arabic characters. An otherwise excellent format is marred by the adoption of a tall, narrow type-face which gives an impression of elegance but is trying to read. The *Journal* is published at Tager Building, Elhami Street, Kasr El Doubara, Cairo, and costs 50 P.T. (10*s*.).

Current Research on Orthoptera

The number of workers now engaged in research on Orthoptera is large and the field of work is very extensive, often resulting in unnecessary duplication of work and in restriction of exchange of ideas. A questionnaire was sent out by the Anti-Locust Research Centre, London, in 1956 to institutions and scientists all over the world known to be engaged in research on Orthoptera, asking them to provide information on the subjects of their research. Of 250 questionnaires sent out, 215 were returned by workers in thirty-seven different countries. As a result, a list of workers and their addresses, indicating the nature of their current work, has been issued by the Anti-Locust Research Centre, under the title "Current Research on Orthoptera", for circulation among all those known to be engaged in research on Orthoptera. The fields of research covered have been divided into seven sections (the figures in brackets showing the number of projects listed in each case) as follows: taxonomy and faunistics (51); anatomy and morphology (26); physiology (biochemistry and metabolism) (37); physiology (nervous system and sense organs) (21); behaviour (46); ecology, biogeography and general biology (76); and pest control (35). When a scientist is engaged in research related to more than one section, separate cross-indexed entries have been made, so that any one section contains a complete list of all known workers in that field. The arrangement within each section is alphabetical. All those listed will receive "Current Research on Orthoptera", further numbers of which will be issued as new or revised entries accumulate. All inquiries and any information for inclusion in the list should be addressed to the Anti-Locust Research Centre, 1 Princes Gate, London, S.W.7.

Swedish Forest Research

Scots pine (*Pinus silvestris*) and Norway spruce (*Picea abies*) form the chief commercial species of the Swedish forests and source of annual revenue obtained from them; it is to be expected, therefore, that these species should be considerably studied in the Forest Research Institute at Stockholm. In the report of the Forest Research Institute of Sweden (Vol. 46. Pp. 572. Stockholm: Statens Skogsforskningsinstitut, 1957) two interesting papers are printed: "Germination Analyses by the X-ray Method of *Picea abies*" and "Seed Development of *Picea abies* and *Pinus silvestris*". The X-ray experiments on the spruce here described are a continuation of work previously carried out at the Institute. The method of predicting the germinative properties of a seed from its X-ray photograph is based on the close correlation between these properties and the morphological characteristics of the seed's embryo and endosperm. The seed was harvested with great care, mostly from northern localities where the less developed seed types are found more frequently. The paper gives full details of the methods employed, with photographs. In the second paper, on the seed development of the two species, the aim of the investigation was to establish the time of fertilization and to follow embryo development during summer and early autumn. The material was collected from trees growing in the vicinity of Stockholm. The report gives data on the time between pollination, fertilization and other interesting facts. It is illustrated with good photographs.

Carlsberg–Wellcome Travelling Research Fellowships, 1958–59

THE directors of the Carlsberg Foundation, in Copenhagen, and the Wellcome Trustees, in London, instituted in 1957 a system of Carlsberg–Wellcome Travelling Research Fellowships, with the object of encouraging friendly co-operation, on an exchange basis, between Danish and British research workers in any branch of the natural sciences which has a bearing upon human and animal medicine. One Fellowship annually is awarded to a candidate from the United Kingdom for a year's work in Denmark and one annually to a Danish candidate for a year's work in the United Kingdom. The stipend may range from £800 to £1,200 per annum (or the equivalent sums in Danish kroner) for whole-time research. Travelling and some incidental expenses are provided in addition. It is intended to make the second two appointments in respect of the academic year beginning September 1958. Inquiries from candidates in the United Kingdom should be addressed to the Scientific Secretary of the Wellcome Trust, 52 Queen Anne Street, London, W.1, from whom further particulars can be obtained. There is no form of application, but candidates should submit a full *curriculum vitae*, together with details of their research proposals and a supporting letter from a senior scientist who is familiar with their work. Completed applications must be submitted before April 30.

Physical Society Handbook of Scientific Instruments and Apparatus

THE annual exhibition of scientific instruments and apparatus of the Physical Society, to be held in the Halls of the Royal Horticultural Society, London, during March 24–27 (see *Nature* of March 8, p. 673) is an established feature of the scientific year in London. The "Handbook of Scientific Instruments and Apparatus, 1958 Exhibition", published in connexion with the exhibition (pp. xvi+284+pp. 84 advertisements. London: The Physical Society, 1958. 6*s*. net), is not only a detailed catalogue of, and guide to, the exhibits, but also a valuable work of reference on recent developments in the design of physical apparatus, providing, moreover, convenient lists of British manufacturers, and of recent scientific and technical books. The "Handbook" is arranged in numerical order of stands at the exhibition and includes a brief description of every item. There are comprehensive indexes both of exhibitors and of all subjects exhibited, and the large section devoted to advertising is in itself a valuable collection of useful information.

Physics in Schools

A JOINT Easter conference of the Education Group and the South Western Branch of the Institute of Physics on "Physics in Schools" is to be held in the H. H. Wills Physics Laboratory of the University of Bristol during April 9–11. The conference will be opened by Sir Philip Morris and addressed by: Mr. A. D. C. Peterson (director of education, City of Oxford) on general education and physics in the sixth form; Mr. D. W. Scott (University of Bristol) on teaching physics in middle and upper forms of grammar schools; Mrs. C. E. Arregger (Hilger and Watts, Ltd.) on the problem of recruiting women as physicists; Mr. W. Llowarch (Institute of Education, London) on the role of practical work in the education of a physicist; Prof. C. H. Dobinson (Reading) on the General Certificate of Education examinations at Ordinary and Advanced levels for future physicists; Prof. G. K. T. Conn (Exeter) on the transition from school to university; and by Dr. J. Topping (principal of Brunel College of Technology, London) on the education of physicists in technical colleges. The conference is open to all who are interested, and accommodation will be available in Wills Hall. Further details and forms of application to attend can be obtained from the Institute of Physics, 47 Belgrave Square, London, S.W.1.

Announcements

THE annual Conference of Science for Peace will be held on March 22 at the Mahatma Gandhi Hall, Fitzroy Square, London, at 2 p.m. Speakers will include Prof. S. C. Harland, Dr. R. L. M. Synge and Dr. E. H. S. Burhop.

SIR HANS KREBS, Whitley professor of biochemistry in the University of Oxford, has been awarded the Gold Medal of the Association for the Advancement of Natural, Medical and Surgical Sciences, Amsterdam, for outstanding scientific achievement. This Medal was instituted in 1840, and the first awards in 1865 were to medical men; later recipients have included Lorentz, van der Waals, Kamerlingh Onnes, Einstein and Sir Henry Dale.

THE Mechanical Engineering Research Laboratory of the Department of Scientific and Industrial Research, East Kilbride, Glasgow, is to hold open days on June 4 and 5. Applications for invitations on either day from representatives of any organization with engineering interests should be sent to the Director.

THE Cornell Summer Laboratory Course in Techniques and Applications of the Electron Microscope for senior workers in the biological and medical sciences is to be given during June 16–July 3 and is being supported by a grant from the National Science Foundation. The course, which is primarily for scientists using the electron microscope in their research work, is under the direction of Prof. B. M. Siegel, to whom all inquiries should be addressed at Rockefeller Hall, Cornell University, Ithaca, New York.

THE scope of the annual Conference on Conservation of Nature in south-east England, which is to be held in the Zoological Society, Regent's Park, London, N.W.1, on April 12, has been extended to include all societies in south-eastern England whether they are members of the South-Eastern Union of Scientific Societies or not. The chair will be taken by the Earl of Cranbrook, and the following addresses will be given: "The Invertebrate Fauna of Chalk Country and its Conservation", by John Sankey; "The Vertebrates of Frensham Ponds and Romney Marsh", by Maxwell Knight; "Possible Nature Reserves in Kent, Sussex and Surrey from a Botanical Ecologist's Viewpoint", by Dr. Francis Rose; and "Conservation in Hertfordshire", by Dr. J. T. Dony. A symposium on the contribution of naturalists' trusts to Nature conservation will also be held. Further details can be obtained from the secretary of the South-Eastern Union of Scientific Societies, Mr. F. Edwards, 53 The Drive, Shoreham-by-Sea, Sussex.

AGEING AND EMPLOYMENT

THERE are many general statements and assumptions about the employment of older workers in industry, but few facts to support those assumptions. An inquiry* carried out by F. Le Gros Clark into the effects of ageing on 251 manual workers in the furniture industry provides information which will, therefore, not only be useful for employers in that industry, but also in other kinds of manufacturing industry.

Most domestic furniture is produced in large factories, which are tending to increase in size and are achieving greater efficiency mainly through the detailed planning and simplification of a large number of successive hand-and-machine operations. Many of the men employed are no longer craftsmen in the traditional sense of that word; they have each been trained on the job to carry out a limited range of operations. Since comparatively few of the men in the mechanized furniture industry are all-round craftsmen, their chances in later life depend partly upon their own adaptability as operatives or labourers, and partly upon the degree of ingenuity and forbearance shown by shop supervisors and foremen in fitting the job to the man.

In consultation with shop supervisors and others, Le Gros Clark examined the industrial and medical records of 251 men whose ages ranged from 55 to 76; they all worked in large factories. They were still employed or had, in a few cases, recently retired. Men were not compulsorily retired at a certain age.

Of the seventy-three men aged from 60 to 64, sixteen had been transferred permanently to jobs of a light character; practically all of them were labourers. Ten other men were only able to remain at or 'near' their normal jobs after some concessions and adjustments had been made. The remaining forty-seven men were still working in the ways to which they had been accustomed for some years past.

An ailing or ageing labourer may be less easy to accommodate than an operative in the same physical condition. He has frequently to be found light labouring work; and that is usually a matter of searching for a job that he can be trusted to carry out at his own pace. The jobs that were found had to be free from the characteristics that had disqualified the labourer from his normal work.

On the other hand, the ten men, for whom some allowances on the job had clearly been made, were mostly operatives. They had not been transferred from their normal departments and some pains had been taken to adjust the work to their physical capacities. The adjustments made often followed on a medical recommendation. A cabinet-maker, for example, had, until the age of 59, been assembling heavy wardrobes; after a hernia operation he had been transferred to light drawer assembly, where he could still, at 63 years, maintain a good pace of output. There was clear evidence of the firm's flexibility in handling older men once deterioration in their health had been checked and their physical condition fairly well stabilized.

Of the forty-seven men still on their normal jobs, Le Gros Clark believed that about one in four were not maintaining the level of output which they had once been capable; these men, too, would have needed some tolerance on the part of their supervisors. At a liberal estimate it appeared that about three in ten of the men in their early sixties were permanently incapacitated for full normal duty; in the case of several others some allowances had to be made.

There was little evidence that men were retiring or even contemplating retirement at the age of 65. Forty-two of the men between the ages of 65 and 69 were traceable from the records. Their patterns of employment were much the same as for those in their early sixties, except that larger numbers of them had to do some light or modified form of work. Sixteen out of these forty-two men (all but one were labourers) had been transferred to light jobs, or else had left their employer in so poor a physical condition that they could scarcely have undertaken any but the lightest work. No long-service employee among them had been discharged on an employer's initiative. Five of the sixteen men were bronchitic; the rest had records of arthritis, hypertension and cardiac debility. When an elderly man had no serious ailment of this nature, it was usually possible to maintain him on his customary work with minor concessions. Another twelve of the forty-two men, mostly operatives, had been provided with work of a distinctly modified kind.

Sixteen men in the records were aged 70 and over. Ten of these had little indication of sickness in their records. This is a common experience throughout industry; such old workers are doubtless in many industries no more than the constitutionally sound survivors of a diminishing generation. Their age had been allowed for in the ordering of their work. In no case was a man in his seventies in full production on what once had been his accustomed job. Each was employed now on very modified or easy-going operations or on tasks of a distinctly light character. Probably not one of these elderly men would have been physically capable of much further work when he did at last retire.

The inquiry clearly showed that some older men in the industry (though not necessarily in other industries) have often to give up their full normal work at about 60. Thenceforth, they only remain employable in furniture production to the extent to which readjustments and transfers can be arranged for their benefit on the shop floor.

In mechanized production of domestic furniture the overall tempo, though it does not necessarily force the pace of a man's individual movements, has to be maintained at a high level. This could easily discriminate against an employee who is ailing or slowing down. By the time they reach their mid-sixties, between one and two out of every five of the men would probably have had to be moved to light operations or to light labouring jobs. By the time they were in the seventies the proportion would be much higher. Similar figures are common in other industries.

In furniture production the continued employability of ageing men depends on two factors. How far are shop supervisors able to break down and reorganize operations in the interests of ageing or ailing men? And what reserves of skill and adaptability have the ageing men themselves? In an industry of this kind it becomes difficult to employ an elderly operative or labourer in the production line, unless he has reserves of adaptability to fall back on. This often depended upon whether these partly skilled men have acquired sufficient craft experience to make them still employable at their age. The craft background of many of the older men has given them assurance of employment. Though a good many of them may have been employed for most of their lives on repetitive and machine work, their early training with hand tools would have sufficed to fit them for transferring at some stage to the finishing shop, repairs or jig-making, according to their degree of skill.

---

* Ageing on the Factory Floor. By F. Le Gros Clark. (Studies of Ageing within the Conditions of Modern Industry.) Pp. 36. (London: The Nuffield Foundation, 1957.)

Against this, where operatives now in their middle lives have not been trained in craftsmanship but only for machine and assembly operations, in later years they may prove somewhat of a problem. Not only will there probably be large numbers of them; they will lack the craft training that would have made them adaptable old employees.

Of the furniture industry as a whole, Le Gros Clark suggests that it will still continue to experiment with new techniques and with new and more efficient factory organization. That, inevitably, means concentration and division of labour; and in a factory where the timing of a large number of successive and converging operations is of paramount importance, it becomes difficult to allow too many operatives to fall too far below a standard level of output. A factory that has incurred heavy overhead charges in the employment of technical and other experts will have streamlined production processes to such an extent that it has to maintain a labour force that is physically capable of the effort and continuity needed. In other words, it has less flexibility than had an old-time workshop in employing its own ailing or ageing operatives.

FUEL CONSUMPTION AND RESOURCES

ONE of the four main purposes of the Clean Air Act is to prohibit in Britain the emission of dark smoke from chimneys, and on February 6 the Minister of Housing and Local Government, Mr. H. Brooke, announced that from June 1 emission of such smoke will be liable to incur a fine of up to £100. This will apply to factories, shops, offices and the funnels of ships and railway engines as well as to domestic chimneys, and from that date all new furnaces installed for burning pulverized fuel, or more than one ton an hour of other solid fuels, must be equipped with grit- and dust-arresting plant approved by the local authority.

These regulations will be applied through statutory instrument No. 167 (*C*2) of 1958, which was laid before Parliament on February 6 and appoints June 1 as the day for the operation of all those provisions of the Clean Air Act which were not brought into force by statutory instrument No. 2022 (*C*19) of 1956. It would seem, however, that much still remains to be done in the way of educating both the public and the local authorities on the importance and benefits of smoke control. In replying to a question in a broadcast discussion the following evening, a group of speakers, which included a member of Parliament, showed a regrettable lack of public responsibility and even ignorance of the fact that domestic fires rarely emit dark smoke as defined in the Act—"as dark as, or darker than, shade two on the Ringelmann chart".

Some reference was made to the importance of smoke abatement in a debate in the House of Lords on February 5. Lord Macdonald of Gwaenysgor, who opened the debate, referred to the importance of the most efficient use of coal and the need for adequate independent scientific advice: he was concerned that this should be available to the Minister of Fuel and Power. Lord Stonehaven, who stressed the value of the National Industrial Fuel Efficiency Service, referred to the savings to be achieved by scrapping the obsolete and inefficient Lancashire boilers still in use, the importance of adequate instrumentation and of competent stokers. Lord de L'Isle insisted that adequate provision for storing fuel is essential if fuel is to be handled economically for central heating systems. Lord Teviot and Lord Hall both referred to the contribution of science to the efficient use of fuel and power resources, but the major interest of the debate centred in the review of these resources which Lord Mills, the Minister of Power, gave in his reply.

Lord Mills suggested that we are approaching a turning-point in that field. Coal is still the foundation of British fuel economy, but while its consumption has increased by 10 per cent since 1948, that of oil has increased by 91 per cent. There is also a tendency for an increasing proportion of fuel to be consumed in refined forms: since 1948, coke consumption has increased by 15 per cent, gas by 27 per cent and electricity by 99 per cent, so that they now account for 40 per cent or more of inland consumption, compared with 25 per cent before the War. Taking all fuels together, 60 per cent is consumed by industry, 13 per cent by transport and 27 per cent by the domestic consumer. Half our coal supplies go to making fuel or energy, 18 per cent to the domestic consumer, 6 per cent to transport and 26 per cent to industry and commerce, which consumed 60 per cent of electricity supply and more than half that of gas.

Lord Mills said that planning must be based on the assumption that the inland demand for coal will continue to grow, but more slowly than that of other primary fuels. Its direct use by the railways and householders will decrease, but there may be large increases in the demand for coal by coke ovens. As regards small coal, stocks amount to 6 million tons, mainly from deep mines, although two-thirds of open-cast coal is in that form, compared with half of the deep-mined coal. Demand for oil is likely to continue, but the power station oil-conversion programme has been reduced by one-third, to the equivalent of 6 million tons of coal. The advent of nuclear power as a third fuel, however, has brought us to the turning point. Nevertheless, nuclear power at present represents very big demands on capital resources and the Minister thought it is entirely right to retard the programme slightly, making up the difference by conventional power stations.

In reply to questions about ZETA, Lord Mills said that while the production of a thermonuclear reaction under controlled conditions has been demonstrated as a practical possibility, the stage reached is comparable with that attained in 1938 when it was first demonstrated that if the atom could be split energy would thereby be released. It took eighteen years to produce the Calder Hall station, which was the prototype of the nuclear power programme, and the problems associated with the controlled release of thermonuclear power are certainly no less formidable. The Government will ensure that full account is taken of all the potentialities opened up by the genius of our scientists and technologists but, even on the most optimistic assumption, it is scarcely conceivable that the present programme for nuclear power will need modification because of these further developments. Lord Mills also suggested that the availability of nuclear power and the removal of the pressure of demand for coal will enable the coal industry to be more selective in its output, both in terms of cost of production and of the kinds of coal produced. He agreed as to the importance of efficiency in consumption and professed himself satisfied with the arrangements for scientific advice. He is setting up a committee to consider improving co-operation between the Area Electricity and Gas Boards, and a pilot plant for underground gasification is under construction.

LIBRARIES

EAST met West at the one-day conference of the Scottish Branch of Aslib in the Scottish Central Library, Edinburgh, on February 7. Five speakers representing overseas countries, but all working in Great Britain, gave papers on different aspects of library and information work in Britain and in their own countries.

Miss Margaret Haferd, Librarian of the U.S. Information Service Library in London, spoke of the different useful services that her establishment could offer by way of information on work in America, and technical books.

The principal speaker of the meeting was Dr. J. C. Malloch, of the Scientific Liaison Office of the National Research Council of Canada. His paper was on "Technical Information in the Modern World". He pointed out how science and technology affect every aspect of daily life, food, clothing, and travel. Even the classicist often does not realize the absurdity of voicing his scorn of science on television and reads Thucydides more easily because a technologist has developed a better printer's ink.

Dr. Malloch suggested that to get the type of general education that is needed, schools and teachers must have available the basic technical information in the right form. He criticized the old dull text teaching Boyle's law, the valency of oxygen or the bones of a frog to students, many of whom will never need this information. He suggested it should be replaced by material which would convey the fascination of scientific discovery and a realization that it really means something to every individual, whatever walk of life they might choose. This is a challenge that cannot be ignored if science is to have the intelligent public support necessary to its development and proper use.

He next spoke about abstracting services, and the tremendous expansion of scientific work in the past twenty years, much of which never appeared in standard journals, and how it had materially altered the situation. While chemists and physicists were served by abstract journals, biologists were badly off. By their own figures, the coverage of *Biological Abstracts* is only about 40 per cent and the publications of the Commonwealth Agricultural Bureaux cover only special fields, generally selectively. The industrial fields of applied science and engineering are virtually without abstracting services. We are now realizing the vast amount of important scientific and technical information that is available in the U.S.S.R., its satellites and China which is scarcely touched by most of the abstracting services and only available with difficulty in any form.

Scientists need help and this is a suitable task for information services, but one which must be carried out by methods agreeable to the working scientists. Many research organizations now make use of public relations or press officers whose duty it is to make known the activities of the laboratories and to present the results to the general public in an understandable form. Discoveries of science only become of immediate importance to mankind when they are available for the general benefit. As a result of nearly fifteen years of experience Dr. Malloch believes that the personal approach of field-officers throughout the country is the best method of disseminating information to factories and industry. Dr. Malloch suggested the motto of a public relations officer of the National Research Council in Canada might well be adopted: "No sooner done than said".

Dr. Malloch then went on to describe in detail the work of the National Research Council of Canada. Its library is the major scientific library of Canada and is operated as a national service. It maintains an index of all the translations made of scientific papers in Canada and co-operates with the Commonwealth Index of Translations.

The afternoon session was devoted to papers on library work in their own countries by three ladies at present working in Edinburgh and Aberdeen libraries. Miss L. Somme, of Hammerfest, Norway, at present in Edinburgh, gave the picture of the growth of libraries in her country since the Second World War. Interest in reading had begun during the war when there was little else to do. Now each county had a main district library and attempts were being made to cover outlying districts by mobile libraries by road and sea. The purchasing and binding of books are carried out by the State. Librarians have a three-year course and, as there is a great lack of librarians, positions are easy to obtain.

Miss T. Visser from Utrecht said that in Holland, owing to religious beliefs, it was quite common to find in any one town three public libraries, one neutral, one Roman Catholic and one Calvinistic, each getting State grants. All, however, are members of the Central Association of Public Libraries, which is responsible for the training and placing of librarians. Special libraries were late in commencing and are now organized by the Netherlands Institute for Documentation and Organization of Libraries. A very useful tool for Dutch librarians is the Union List of Periodicals held in the 166 libraries in the Netherlands maintained by the Royal Library at the Hague.

Miss De Silva, at present in Aberdeen, spoke of the differences between the libraries in Ceylon, Kenya and the United Kingdom. She pointed out that the two eastern countries were backward and not well equipped. Both countries were similar in basing their libraries upon British methods and Ceylon was the more advanced. There are three libraries in Kenya, the Macmillan Library for Europeans, one for Africans only and one general. J. R. K. PIRIE

EXOTIC FOREST TREES IN GREAT BRITAIN

IT is held that Great Britain contains a larger number of exotic trees than any other country, some of which have been well known for a long time. These have adapted themselves to soils and climate so well that they are regarded as indigenous species. This abundance conceals our poverty of native trees, especially conifers, among which the only natives are the Scots pine, the yew and the juniper, the latter little more than a straggling bush. Among broad-leaved trees the difference is not so great, but even in this group familiar trees such as the sycamore, the horse chestnut and the plane have been introduced in historic times. The sycamore is notable for its rapid growth in youth, for the lovely tree produced and its great fertility, young seedlings springing profusely from the seed shed in most years.

The Forestry Commission has recently published Bulletin No. 30 on "Exotic Trees in Great Britain", prepared by Messrs. James Macdonald, R. F. Wood, M. V. Edwards and J. R. Aldhous for the British Commonwealth Conference held last July in Australia and New Zealand (H.M. Stationery Office, 1957). The Scots pine formed forests in the Highlands of Scotland, but the Norway spruce, now so common in Britain, was absent. The beech was native only in the south of England and absent from the deciduous forest dominated by oak in the rest of the country. This is in marked contrast with France, where the great oak and beech forests are the glory of that country. Part 1 deals with general considerations affecting exotic forest trees in Great Britain; Part 2 exotic coniferous trees; and Part 3 exotic broad-leaved trees in Great Britain.

The poverty of the tree flora of the British Isles is attributed partly to geographical situation and partly to recent geological history. The introduction of exotic species was at first due to individuals who brought them in for æsthetic purposes on their estates. More recently, commercial motives have increased the rate of introduction of some species such as the sitka spruce and Douglas fir from North America and the Japanese larch. The European larch came in much earlier and was planted on private estates, but the Norway spruce and the silver fir were imported during the past two centuries.

The sitka spruce has been largely used in the twentieth century by the Forestry Commission in planting the new forests of Britain, as have the Japanese larch and the Corsican pine. Thirty-eight genera of conifers and twenty-two genera of broad-leaved trees have been introduced into Britain.

EUROPEAN ORGANIZATION FOR NUCLEAR RESEARCH

REPORT FOR 1956

THE second annual report of the European Organization for Nuclear Research (CERN), covering the period to the end of 1956*, is—as Prof. C. J. Bakker, the director-general of the Organization, remarks in his brief introduction—a straightforward account of development during the year, which indicates that rapid progress has been made in accordance with the plan outlined in the previous annual report (*Nature*, **178**, 902; 1956). However, several years of intensive scientific and technical work still lie ahead before Europe's great joint laboratory for advanced nuclear research can begin to operate fully. Except for the high-frequency system the synchro-cyclotron was practically completed; it was expected to come into operation during 1957. The buildings for the proton synchrotron were also nearly finished and orders for most of the components of the accelerator have been placed. The many illustrations and photographs given in the annual report show clearly the remarkable progress made in the construction of these two large accelerators and their associated buildings, and much detail of the layout and characteristics of the machines is also given in the two sections of the report devoted specially to them.

The purpose of the two-week symposium on high-energy accelerators and pion physics, organized by CERN and held in Geneva during June 1956, was to gather physicists from all over the world and thus enable the Organization to start playing the part for which it was intended as an international centre of advanced studies. 319 scientists from twenty-two countries, including some fifty American and an equal number of Russian scientists, attended. Most of the papers presented had been pre-printed either in English or French and were circulated before the conference. The discussions were recorded, and the proceedings were afterwards published in full in two volumes (see *Nature*, **179**, 283; 1957). It is proposed to hold a similar symposium in 1958. During the first week the principles and methods used in the construction of high-energy accelerators were discussed, and during the second week particle-detecting equipment and high-energy nuclear experimental research with special reference to pion physics. The section of the annual report describing the symposium includes a summary of the main contributions and of the new advances in research discussed, and a list of the titles of the papers which were presented by members of the staff of the Organization is given in an appendix.

---

* Second Annual Report of the European Organization for Nuclear Research (CERN), 1956. Pp. vi+71 (19 plates). (Geneva: European Organization for Nuclear Research, 1957.)

No major change in the internal structure of the Organization took place during 1956. Theoretical work was carried out both under the direct control of Prof. Bakker at Geneva on cosmic rays and in the Theoretical Study Division at Copenhagen ; the other five Divisions consisted of the Proton Synchrotron, Synchro-Cyclotron, Scientific and Technical Services, Site and Buildings, and Administration. The number of the staff increased from 260 to 396, and in addition there were eight half-time workers, fourteen consultants and twenty-two Fellows. Thirty-one scientific articles were published and a very large number of lectures and colloquia, all of which are listed in the annual report, were arranged.

In the field of equipment the set of two cloud chambers was successfully completed by the Scientific and Technical Services Division and will be used for experiments on K-mesons. The Division has been studying the techniques of production and handling of liquid hydrogen and liquid helium for low-temperature work, and a liquid-hydrogen plant with a capacity of 20–40 litres/hr. is being built. An experimental liquid-hydrogen bubble chamber, 10 cm. in diameter, and later a larger chamber, 30 cm. in diameter, are to be constructed. Following Harwell and Saclay, and with a view of establishing interchangeable methods and means of computation with these two establishments, the Organization has ordered a 'Mercury' electronic computer, and an experienced mathematician-physicist has been recruited to direct the Computer Section of the Division. In addition, two engineers of the Division spent four months with the electronic groups at Harwell and Saclay.

EMBRYOLOGY OF POGONOPHORA AND CLASSIFICATIONS OF ANIMALS

By DR. S. M. MANTON, F.R.S.
Department of Zoology, King's College, London, W.C.2

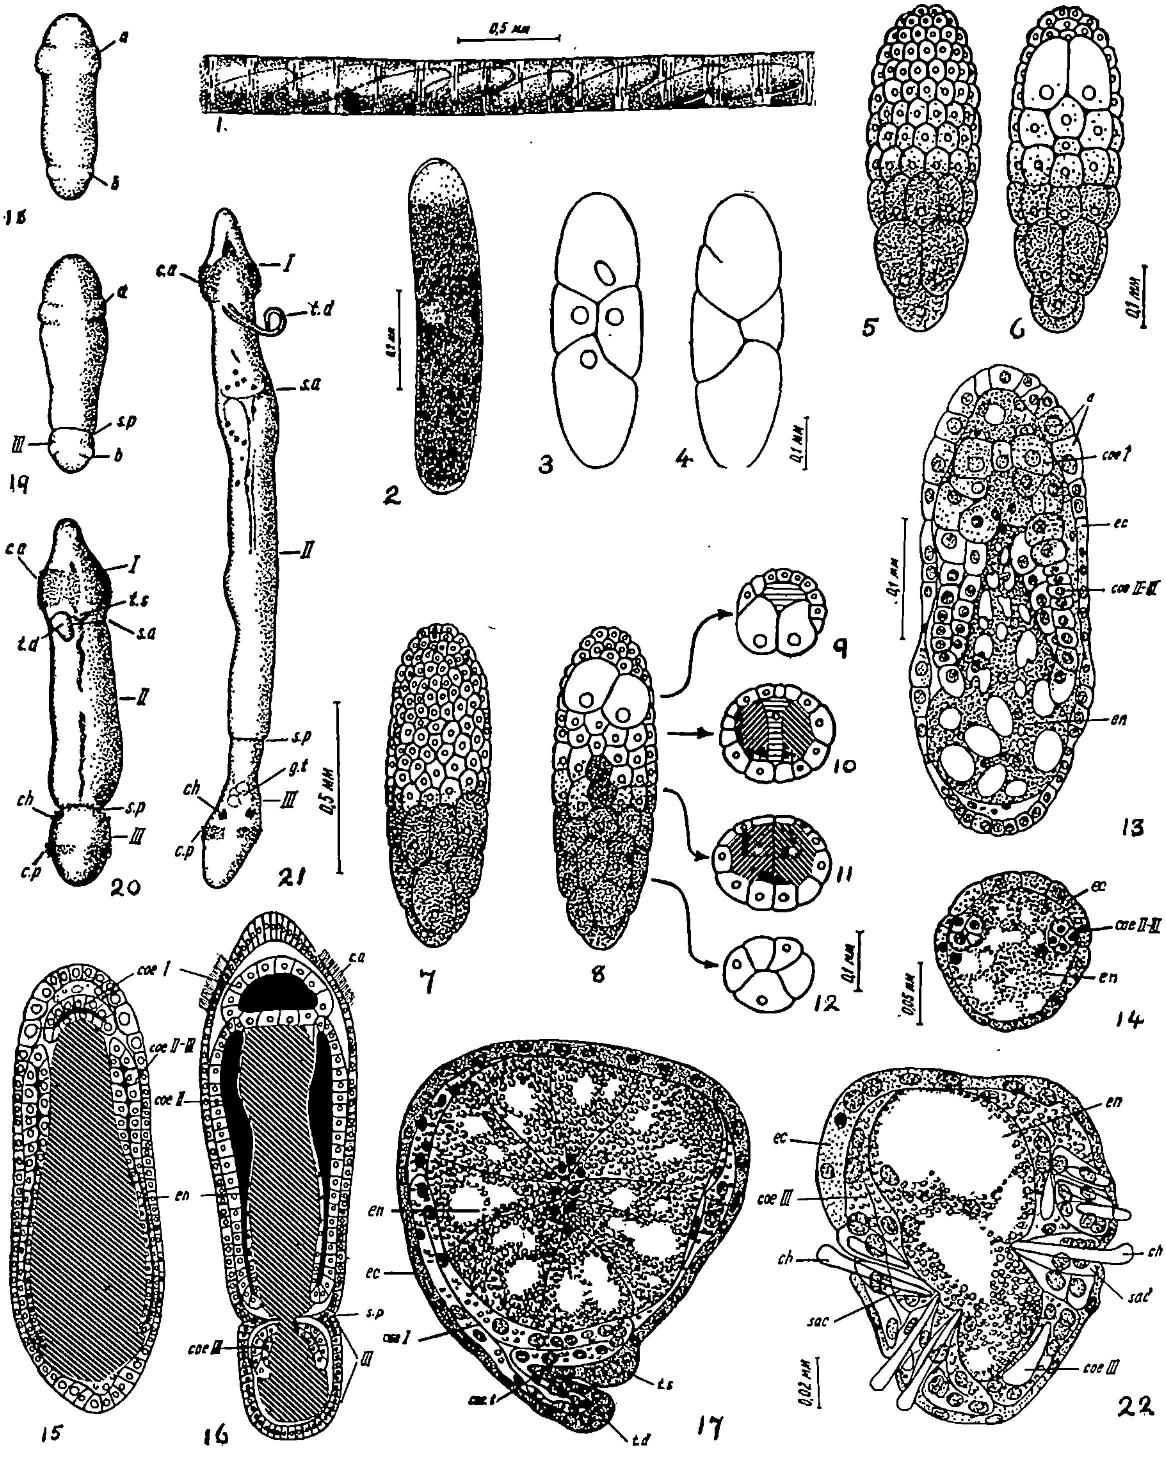
THE past twenty years have considerably widened zoological conceptions concerning the types of animals which are phylogenetically associated with the echinoderm-chordate stem. Kozlowski[1] (1938, 1947) dissolved the matrix from certain graptolites and cleared them, so demonstrating a similarity in budding and tube structure to *Rhabdopleura*, thus suggesting a protochordate rather than a coelenterate affinity for this great group of fossil animals (see also Bulman[2]). At that time much had been found out concerning evolution within the graptolites, but no clear evidence had been obtained as to the grade of organization of their soft parts, so that their systematic position was obscure. The class Pogonophora was described in 1937 by Johansson[3]. But it was the anatomical work of Ivanov in the University of Leningrad[4], on two orders of Pogonophora, collected from deep water in the north-west Pacific, which provided a sufficiency of detail both to demonstrate their place in the animal kingdom near to the Enteropneusta, and to show the extraordinary occurrence of extracellular digestion and absence of a gut in a non-parasitic triploblastic animal.

Recently, Ivanov[5] has given embryological details of a certain number of developmental stages of Pogonophora from the Okhotsk Sea, the preservation of which has been sufficiently good for sectioning. He stresses the incompleteness of the series and imperfections of fixation ; but his results are of such interest that a summary is given below, together with reproductions of some of the figures. Reference must be made to the original publication in Russian for further details.

About 32 batches of eggs, mainly of *Siboglinum caulleryi*, have been studied. The eggs in each batch, up to 42 in number, lie in a row inside the parental tube distal to the head of the mother (Fig. 1), where they undergo most of their development. No free-swimming larvæ are formed. The bilaterally symmetrical egg, much elongated in *Siboglinum*, is heavily yolked ; the nucleus (Fig. 2) lies nearest to the concave side of the egg. The darker distal pole of the egg gives rise to the anterior end, and the more yolky proximal pole to the posterior end of the young adult. Fertilization is presumed to take place in the tube. The nucleus migrates to the distal end of the egg, and after fertilization returns to the middle region ; the egg then becomes invested by a soft vitelline membrane. Development within each clutch is synchronous.

Cleavage is total, unequal and appears to be 'determinate'. There is no trace of either the spiral or typically radial type of cleavage, and the unique pattern appears to be anything but primitive. The egg shortens and divides diagonally, and unequal cleavages beyond the 4-celled stage are not synchronous (Figs. 3 and 4). Bilateral symmetry is marked at the 80–85 celled stage, large cells lie at the posterior end and on the convex side, and two very large cells are situated towards the anterior end on this side (Figs. 5 and 6, same embryo).

By the 130- to 140-celled stage internal cells are established, presumably by delamination or by overgrowth. Three large endodermal cells, one extending in front of the other two, fill most of the interior of the embryo, and contain the bulk of the yolk (ruled in three different directions in Figs. 9–11). Two surface cells rich in yolk lie in the middle of the convex side (dark in Fig. 8). In addition, two small groups of cells, presumed to be mesenchyme, are situated as shown in Fig. 10. The posterior outer cells are rich in yolk, and the large pair of anterior cells (Figs. 8 and 9, same embryo) remain unchanged for a while ; their fate is unknown. This stage represents a gastrula, but a blastopore is not formed.



Figs. 1–16 and 18–21, egg and embryos of *Siboglinum caulleryi*; Figs. 17 and 22, sections of *Oligobrachia dogieli*; Figs. 3 and 4, concave and convex sides, respectively, of same embryo; Figs. 5 and 6, concave and convex sides, respectively, of same embryo; Figs. 7 and 8, concave and convex sides, respectively, of same embryo; Figs. 9–12, T.S. of embryo at the levels indicated by arrows; Figs. 13 and 14, L.S. and T.S., respectively, of embryo younger than Fig. 18; Fig. 15, diagrammatic L.S. of slightly younger stage than Fig. 18; Fig. 16, diagrammatic L.S. of same stage as Fig. 19

The next available stage (Fig. 13) shows the establishment of the coelom, by a method very similar to that seen in the enteropneust *Dolichoglossus pusillus*. An inner yolky endodermal mass of cells is continuous with a median anterior enterocoelic pouch (*coel.* 1, Fig. 13), and from it paired tubular outgrowths form the common rudiments of the second and third pairs of coelomic pouches (*coel.* II–III, Figs. 13, 14 and 15). Later, the second and third pouches separate as shown (Fig. 16). A transitory minute endodermal cavity is formed anteriorly (*en.*, Fig. 17) but elsewhere the endodermal cells remain irregular in a solid mass.

Externally the embryo of *Siboglinum* develops two girdles of short dense cilia, the anterior one (*c.a.*) round the future protosoma (I) arising from two rows of ectodermal cells (*a*), and the hinder one (*c.p.*) round the developing metasoma (III) arising from only one row (Figs. 13–16, 18–21). A furrow (*s.p.*) then separates the meta- from the mesosoma (Figs. 16 and 19), followed by elongation of the mesosoma (II, Fig. 20), and another furrow (*s.a.*) appears between the proto- and meso-soma; internal septa develop at these furrows. The rudiment of the single adult tentacle (*t.d.*) protrudes on the ventral right side of the prosoma; a transitory small fellow one (*t.s.*) develops no further in *Siboglinum* (Figs. 17 and 20). In *Oligobrachia* pairs of tentacles develop progressively on either side of the initial ventral pair, on the postero-ventral arms of a U-shaped tentacle base, a process continuing throughout life. Diverticula of the median first coelomic sac pass into the tentacles (*coel.* 1, *coel. t.*, Fig. 17). Part of the dorsal surface of the mesosoma becomes ciliated. Mesosoma, metasoma and tentacle then elongate (Fig. 20), and perhaps the embryo leaves the parental tube shortly after this stage, moving by muscles of the body wall. The ciliated girdles are lost, and the ectoderm, rich in gland cells (*g.t.*, Fig. 21), may be ready to secrete a new tube for the young animal. No mouth or anus develops, and the endoderm disappears as its yolk content becomes used up.

Muscles of the body-wall develop from the coelomic mesoderm below the ectoderm. Several groups of ectodermal cells secrete provisional chitinous setae (*ch.*) on the metasoma, one seta from each group of cells (*sac.*, Figs. 20, 21, 22). The distal ends of the setæ finally project through the ectoderm, but no conspicuous muscles move these setæ, although some fine ectodermal fibrils to their inner ends may be seen.

Few details are available of the ontogeny of the nervous, vascular or genital systems, but the remarkable features just described amply confirm the existence of enteropneust resemblances. The Pogonophora clearly share with *Dolichoglossus kowalevskyi* and *D. pusillus*: (1) a suppression of pelagic larvæ owing to an abundance of yolk sufficient to maintain a long embryonic development, the provisional girdles of cilia and dorsal mesosomatic tract of cilia of the pogonophoran embryo representing those of the tornaria larva; (2) the anterior median and paired second and third coelomic pouches arising in a similar manner; (3) an early division of the body into three regions, the metasoma being small when first differentiated, and elongating later to form the greater part of the adult body, as occurs also in *Amphioxus*. These features place the Pogonophora squarely among the echinoderm–pterobranchiate–protochordate–chordate group of animals, and no question remains of annelic affinity. Their status as an independent phylum is dictated by: (1) the absence of adult alimentary canal, mouth and anus; (2) the presence of tentacles on the prosoma and not on the mesosoma as in *Cephalodiscus*; (3) the distribution and type of coelomoducts; (4) the positions of the brain and heart (see Ivanov, 1955[4]). The provisional setæ on the metasoma of Pogonophora show no exact similarity in either development or associations with those of annelid parapodia. Setæ are also found in Brachiopoda, and here as well as in Pogonophora have doubtless been convergently acquired. The bilateral symmetry of the egg of *Siboglinum*, the cleavage pattern, and the utilization of the endoderm to carry the embryonic food supply only, indicate the highly specialized nature of the Pogonophora, and the single adult tentacle of *Siboglinum* is clearly a secondary specialization within the group.

Dr. A. V. Ivanov is to be congratulated on achieving such important results from difficult material obtainable only from abyssal waters, and it is to be hoped that future expeditions organized by the Institute of Oceanography of the U.S.S.R. will yield further material which may fill the gaps in Ivanov's series of developmental stages.

Jägersten[6] has described one developmental stage (three specimens) from the tube of an undetermined species of *Siboglinum* collected from Norwegian waters. This stage possesses external ciliation and a yolky cavity-less endoderm as in *S. caulleryi* (Figs. 18–20); no tentacles are present but an anterior furrow is shown. Ivanov's fuller account indicates that this stage is in fact an embryo, and not a larva about to leave the tube, or an asexually produced bud. Jägersten's embryo possesses more provisional setæ than *S. caulleryi* and he notes their differences from setæ of annelids.

Ivanov and his countrymen use the term 'Deuterostomia' to designate that section of the animal kingdom frequently referred to in Great Britain as the echinoderm–chordate stem. We need some other terms to replace the outworn Protostomia and Deuterostomia. The anus may have an association with the blastopore in typical echinoderms, protochordates and vertebrates; but so has it in some quite unrelated invertebrates, and the spirally cleaving invertebrates and the arthropods are not all protostomial. The recognition of relationships within these two great assemblages of animals is universally accepted, although it does not rest on the fate of the blastopore. Closely related animals can be quite different in the fate of the blastopore and origin of mouth and anus[7]. Hyman's[8] definitions of these assemblages, Protostomia, "the groups with determinate cleavage, and mesoderm originating from definite cells or bands", and Deuterostomia, "the groups with indeterminate cleavage and mesoderm and coelom arising as entodermal sacs", also do not fit the facts; the occurrence of 'determinate' cleavage alone can be found in very different form in unrelated groups, such as ascidians, annelids, Pogonophora and molluscs, and mesoderm and coelom formation can scarcely be summarized adequately in these words.

The life-history of Pogonophora shows a clear relict of a tornaria type of dipleura larva which has become embryonic. The cilia are no longer locomotory, and must circulate water to some extent between closely packed embryos before they leave the parent. We cannot agree with Hyman in assigning an ancestral status to the dipleura larva for the whole echinoderm-chordate group of animals. Garstang[9], de Beer[10] and others have discussed the fallacy of regarding larval forms as representing ancestral adults. The tornaria characters appearing in the pogonophoran embryo can only represent the larval features of the ancestors of this group.

As more information on the little-known phyla becomes available it is perhaps remarkable to find so many groups related to echinoderms and vertebrates using the protection of either floating or fixed tubes or tests (Graptolites, Pterobranchia, Pogonophora, Tunicata), or evading competition by burrowing into the substratum (Enteropneuta, Cephalochordata) or retiring to abyssal waters (Pterobranchia, Pogonophora). It appears to have been the evolution of mobile personal armour and effective locomotory mechanisms which have enabled vertebrates and echinoderms to succeed in all manner of open and competitive environments.

FLUORESCENCE OF THE TOXIN OF *CLOSTRIDIUM BOTULINUM* AND ITS RELATION TO TOXICITY

By Dr. DANIEL A. BOROFF and Dr. JOHN E. FITZGERALD

Divisions of Microbiology and Biophysics, New England Institute for Medical Research, Ridgefield, Connecticut

THE toxins of *Clostridium botulinum* have been studied extensively in recent years, but no special chemical groups or unusual structural characteristics have been demonstrated to account for their extraordinary biological potency[1,2]. We have recently observed that *botulinum* toxin is fluorescent when activated by a specific wave-length in the ultra-violet, and the intensity of the fluorescence is related to the toxicity. Since chemical modification or preparative procedures which diminish the fluorescence also diminish the toxicity, this fluorescent property of the toxin makes possible a new chemical approach to the study of the toxic portion of the molecule. Furthermore, the fluorescence of the toxin can serve as the basis for a physical, *in vitro* method for measuring the toxicity of a preparation.

Type *C* toxin was prepared and purified by methods previously described[3,4]. The final preparation contained 2 × 10^7 minimum lethal dose mgm. nitrogen assayed by intraperitoneal injection in 20-gm. white mice. Measurements of survival time of 20-gm. white mice injected intravenously with 0·1 ml. of serial dilution of toxin were made. An unusually interesting correlation became evident when it was demonstrated that the logarithm of the minimum lethal dose administered showed a nearly linear relationship to the time of survival (Fig. 1). This was used as a standard toxicity curve. Fluorescent measurements were made in the 'Aminco–Bowman' spectrophotofluorometer and calibrated for wave-length and intensity by a standard quinine solution[5]. For this instrument, maxima of activation and fluorescence for the toxin occurred at 287 mμ and 350 mμ, respectively. The fluorescent intensity measured in arbitrary units is linear for toxin concentration below 45 μgm. of protein per ml. (1·4 × 10^5 minimum lethal dose). Above this concentration, fluorescent quenching occurs. Except where otherwise indicated, the toxin was dissolved in phosphate buffer (*p*H 6·8, μ 0·15). For this and the other solvents used, correction for blank was negligible. Scattering, which occurs at incident wave-length, is sufficiently separated from the fluorescent maximum to be non-contributing. The fluorescent intensity values are reproducible within 5 per cent even for different preparations of the toxin.

Botulinum toxin retains toxicity at acid or moderately alkaline *p*H values but is rapidly detoxified above *p*H 10. Fluorescent intensity is also retained below *p*H 10, but at higher *p*H-values there is a marked decrease in fluorescence corresponding to the loss in toxicity (Fig. 2). Neither the fluorescence nor

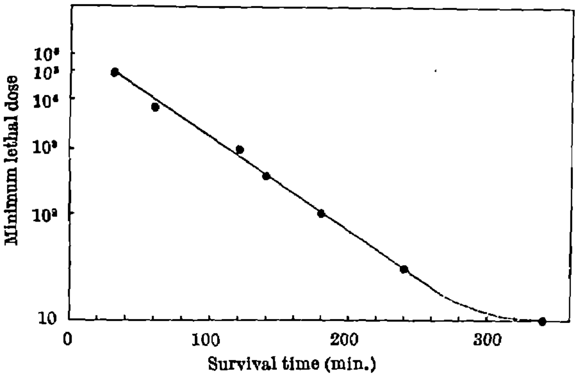

Fig. 1. The survival time of 20-gm. white mice after intravenous injection of dilutions of *Clostridium botulinum* toxin

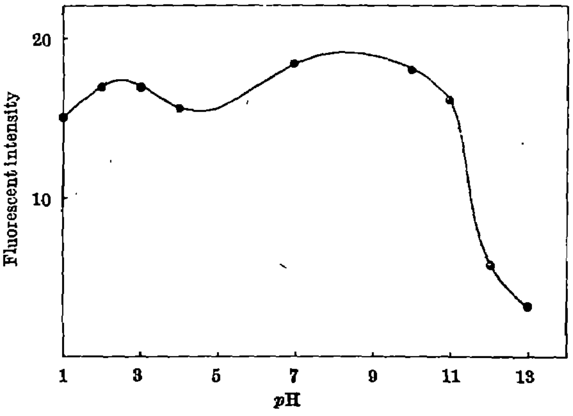

Fig. 2. Effect of *p*H on fluorescent intensity of *Clostridium botulinum* toxin

the toxicity is restored by prolonged dialysis against the original solvent in which the untreated toxin is fully potent. The significance of the smaller decrease in fluorescence near *p*H 5 is not yet clear, and *in vivo* measurements are not sufficiently sensitive to determine that a similar decrease occurs in the toxicity.

Although normal rabbit serum and specific rabbit antiserum (antitoxin) exhibit their own fluorescence, it was shown that the latter decreases the fluorescence of toxin while the former does not. In Fig. 3, the fluorescent intensity of dilutions of normal rabbit serum and specific rabbit antiserum alone are identical (curve *C*); curve *A* shows fluorescent intensity of dilutions of normal rabbit serum plus a constant amount of toxin, while curve *B* shows fluorescent intensity of dilutions of specific rabbit antiserum plus a constant amount of toxin. All samples were incubated at 4° C. for 18 hr. Curve *C* shows a simple increase of fluorescence as the concentration increases (in the non-quenching region). Curve *A* shows a simple additive effect of the fluorescence of the toxin plus the fluorescence of the normal rabbit serum. Curve *B* shows a progressive decrease in the toxin fluorescence as the concentration of specific rabbit serum is increased, suggesting that a combination of toxin and antitoxin has occurred. At the point of fluorescence extinction of the toxin, the toxicity was reduced from the initial value of 100,000 × minimum lethal dose to less than 10 × minimum lethal dose. The slow rate of this reaction is indicated by the fact that an incubation period is required since there is no diminution of toxin fluorescence immediately after the addition of rabbit antiserum.

Since metallic ions interact with active protein groups, a number of metal salts were tested for their effect on fluorescence. The toxin was mixed with dilute solutions (0·01–0·001 *M*) of copper sulphate, cadmium chloride, ferric and ferrous chlorides, chlorides of magnesium and mercury, and zinc sulphate. Of these, only ferric ion showed any effect on fluorescence or toxicity. This ion abolished the fluorescence at 10^{-3} *M* and produced significant depression of fluorescence at 10^{-7} *M*. The effect was immediate and showed no change with time. Ferric ion also depresses toxicity, but at higher concentrations (more than 0·005 *M*) (Fig. 4). The possibility that the reaction of the toxin with ferric ion in low concentrations is reversible and occurs *in vivo* has been considered. Preliminary experiments show that 'pre-loading' mice by intravenous injection of 0·3 ml. of 0·01 *M* ferric ion reduces the effectiveness of the toxin by more than 90 per cent.

The effect of antitoxin on the fluorescence of *Clostridium botulinum* toxin. ○, Fluorescent intensity of dilutions of normal rabbit serum alone; ●, specific rabbit antiserum alone (curve *C*). Fluorescent intensity of dilutions of normal rabbit serum plus constant amount of toxin (curve *A*). Fluorescent intensity of dilutions of specific rabbit antiserum plus the same amount of toxin used in curve *A* (curve *B*). Fluorescent intensity in arbitrary units; that of toxin alone = 32

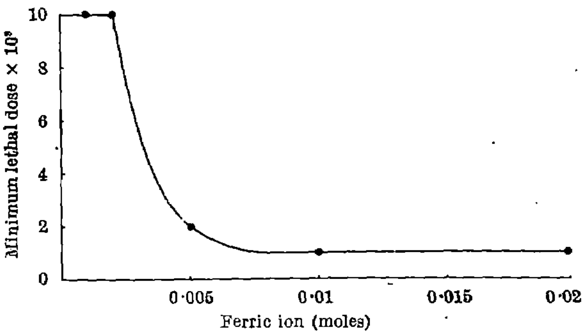

Fig. 4. The effect of ferric ion on the toxicity of *Clostridium botulinum* toxin

The dependence of fluorescence on toxicity was also demonstrated by two other means. *Cl. botulinum* when grown under certain conditions of subculture results in a progressive decrease in toxicity of the culture supernates, which is not due to a decrease in bacterial protein. The supernatants of these cultures subjected to our method of toxin purification yield material which appears similar to the substance obtained from fully toxigenic cultures, except that these preparations showed the above-mentioned decrease in toxicity with a corresponding decrease in fluorescence. The fluorescence in these supernatants was shown to decrease corresponding to the decrease in toxicity. Also, toxoid prepared by treatment of the toxin with 0·5 per cent formaldehyde showed no fluorescence.

Since the toxin is a protein and appears to contain no unusual chemical groups[3], the fluorescence is presumably due to the content of amino-acids which fluoresce in the region of the maxima observed, namely, tryptophan, phenylalanine and tyrosine. Purified serum albumin and bovine fibrinogen were also found to fluoresce in this region. The fluorescence intensity of the proteins, however, is much greater than can be accounted for by the sum of the fluorescence of these amino-acids measured alone under the same conditions and in the same concentrations in which they occur in the proteins. Hence, the spatial configuration of these amino-acids in the protein molecule, or of some other otherwise non-fluorescent amino-acids, is probably responsible for the fluorescence produced.

In these experiments with *botulinum* toxin, procedures which diminished the toxicity also diminished the fluorescence. This may indicate that alteration of the gross structure of the protein molecule destroys fluorescence and toxicity, and both these phenomena are properties of the intact molecule. It is more probable, however, that the relationship is more intimate and that some specific region of the molecule responsible for the toxicity is also responsible for the fluorescence.

THE MESOPAUSE REGION OF THE IONOSPHERE

By Dr. J. B. GREGORY

Department of Physics, University of Canterbury, Christchurch, New Zealand

A PULSE sounding apparatus, specially designed for the study of the lower ionosphere and capable of detecting reflexions the voltage coefficient of which exceeds 5×10^{-6}, has been maintained in operation near Christchurch, New Zealand (43° S.), since early 1955. Transmissions are made at a fixed frequency of 1·75 Mc./s. Initial results previously described[1] have now been largely confirmed. Extended observations suggest that there are some features of the ionosphere below 100 km. that deserve closer study in different latitudes. The most important of these features is the continuous existence of ionization throughout a range of heights commencing at a little above 80 km. and extending to about 100 km. Fig. 1 shows a plot of the lower boundary heights of reflexions from this region for four undisturbed days in the various seasons. The strength of the reflexions from this region varies through a range of about 70 db. Between 85 and 90 km., reflexions with a coefficient greater than 10^{-3} have been noted during day and night on many occasions. I have shown[2] that these partial reflexions detected at vertical incidence, together with those from lower heights, are the medium-frequency counterpart of the oblique scattering of very-high-frequency waves now utilized for communication purposes.

A characteristic of the reflexions near 85 km. is the formation of a sharp lower boundary, which may persist for several hours with little change in height. This discontinuity in ionization density usually continues during daylight hours despite the presence of reflexions immediately below it. The 1·75 Mc./s. observations indicate that the major change in ionization density below the *E*-region is more often near 85 km. than elsewhere. At night, the lowest height at which reflexions are detected is often close to 85 km. Initial observations suggested that the night boundary did not descend below 80 km., but later work has shown that ionization at night does remain to a much greater extent and at lower heights than has previously been reported. Fig. 2 shows a record taken at 0145 N.Z.S.T. on May 22, 1956, in which a distinct region at 73 km. is visible in addition to rapidly fading reflexions at 85 km. and sporadic-*E* at 105 km. The lower reflexions were present at heights between 73 km. and 75 km. at hourly intervals of observation throughout the night of May 21–22, with a reflexion coefficient which varied between 5×10^{-5} and 5×10^{-4}. Numerous examples, mostly in winter, are available of reflexions from as low as 75 km. The lowest recorded height at night occurred on May 27, 1957, at 0530 N.Z.S.T., that is to say, about eleven hours after sunset and two hours before sunrise, when weak reflexions from a height of 67 km. were noted during the 8 min. required for a routine observation of heights and strengths of reflexions. This particular event occurred during a 24-hr. period which was part of a group of winter days of high absorption, and during this period the lower boundary of the main reflecting region below the *E*-region did not rise above 78 km.

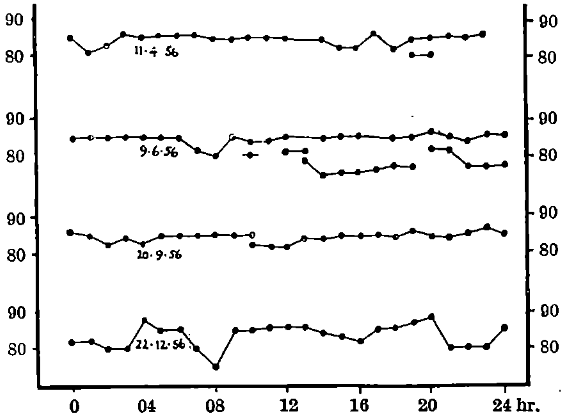

Fig. 1. Lower boundary heights of the mesopause layer at all seasons

Fig. 1 shows that the reflexion heights between 80 and 90 km. are largely independent of solar control. It is thus necessary to show how ionization of low recombination-rate may always be found, though in varying quantities, within limited heights below the *E*-region. A possible origin of this ionization is dust or debris, composed of elements of low ionization potentials such as are found spectroscopically in

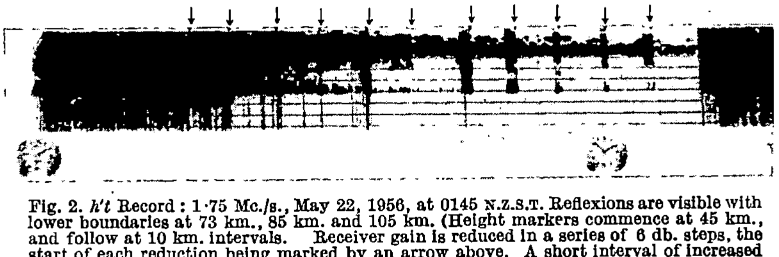

Fig. 2. *h't* Record: 1·75 Mc./s., May 22, 1956, at 0145 N.Z.S.T. Reflexions are visible with lower boundaries at 73 km., 85 km. and 105 km. (Height markers commence at 45 km., and follow at 10 km. intervals. Receiver gain is reduced in a series of 6 db. steps, the start of each reduction being marked by an arrow above. A short interval of increased gain precedes each reduction)

meteors. When photo-ionized, this material would recombine only by radiative processes. Observed electron densities appear to require concentrations of dust that are unlikely to be produced by ablation of meteors detected visually or by means of radar ; and hence an extra-terrestrial origin is supported. The existence of meteor atoms as a constituent of the *E*-region has been suggested by Nicolet[3].

The increase in concentration of this dust near 85 km., and the formation of a sharp lower boundary at this height, may be explained as follows. In the temperature inversion above the mesopause, vertical diffusion of dust will be slow, and certainly much less than any movement in horizontal directions. The concentration of dust will increase with decreasing height. In the mesodecline, vertical diffusion will occur at a much greater rate, so that any material which diffuses across the mesopause is likely to thin out rapidly. Hence maximum concentration will occur close to the mesopause (near 85 km.). Among my records are a number of features which are accounted for in qualitative fashion by the processes outlined. These include the formation of a sharp boundary, stratification of reflexions above 85 km., and a variable concentration of ionization from day to day at heights below 70 km. The optical scattering experiments of Bigg[4] support the existence of dust at the mesopause. Little is known of the incidence of dust on the Earth's atmosphere, and knowledge of horizontal transport within the atmosphere will be required before the radio method can give information as to its rate of arrival. Sufficient evidence is available to confirm its existence, and to show that physical rather than photo-chemical factors are responsible for the formation of a mesopause region of the ionosphere.

The enhancement of ionization at heights above 67 km. during winter days of high absorption has been demonstrated by me[1]. The low recombination-rate at night of this ionization, revealed by later work, raises the possibility that the extra constituent present during these periods may also be meteoric dust. If this proves to be the case, then the seasonal and latitude aspects of the high-absorption effect will require an explanation in terms of the upper-atmosphere circulation pattern. I believe that my records show some evidence that horizontal transport of the extra constituent may occur above the mesopause, but more work is required to confirm this view. At present, available information relating to atmospheric sodium[5], which shows a peak of radiation intensity near the mesopause, suggests that transport from the pole towards the equator is likely.

The suggestions advanced in this communication are being pursued, and results of a detailed analysis of a year's observations of the lower ionosphere will be presented at a later date.

USE OF 'BROOD PATTERNS' IN RESEARCH ON CHEMICAL MUTAGENS

IN a recent article in *Nature*[1], Drs. O. G. and M. J. Fahmy have used a few brood patterns of mutation frequencies after treatment with certain sulphonates for building up far-reaching speculations on the action of these compounds. Since I have had many years of experience with this kind of approach to the study of chemical mutagenesis[2], may I be permitted to pronounce a warning against its incautious use. My points of criticism are too numerous and too technical to be discussed fully here ; they will be published *in extenso* elsewhere[3]. Here I only want to enumerate briefly the most important ones.

(*a*) There has been no proof that the methods used by Drs. Fahmy result in repeatable brood patterns in replicate experiments. On the contrary, the reference to these 'standardized' methods is to a paper[4] which illustrates strikingly the lack of uniformity in replicate experiments, and no modifications of the method have ever been reported.

(*b*) The claim that with the methods used "spermatogonia differentiate into mature sperm within a period of 15 days" is wholly unsubstantiated. It leaves out of account the influence which different kinds of chemical treatment may have on the rate of sperm release. An example that even one and the same chemical in different doses may produce different brood patterns is shown in Fig. 1 of Drs. Fahmy's article[1] : after treatment with the lower dose of methyl methanesulphonate, mutation-frequency dropped from 5·2 per cent in the third brood to 3·9 per cent in the fourth ; after treatment with the higher dose these two broods had the same frequency of lethals. Drs. Fahmy base their interpretation of brood patterns on an investigation[5] in which the brood pattern for triethylene melamine was interpreted by reference to the histological picture of the treated testis, a method which—unsupported by genetical tests[6]—leaves a wide margin of error. In any event, its results are applicable to triethylene melamine, and to that substance only ; they have no validity for other substances.

(*c*) There is no proof for the claim that after treatment with chloroethyl methane sulphonate (*CB* 1506) the fifth brood is drawn from the latest spermatogonia, "just before they started metamorphosing into spermatocytes". It is true that this brood had been drawn from treated spermatogonia, because it contained bunches of visible mutations. But there is no reason for believing that it was "the first brood" to do so ; for since the previous brood did not contain any visible mutations at all[7], it is hard to see how they could have formed bunches. In addition, the absence of bunches from limited sperm samples cannot be taken as proof that the treated cells had passed the spermatogonial stage ; for late spermatogonia give bunches of two, which can be detected only in very large-scale tests.

(*d*) The application of statistical methods to brood patterns has to be carried out with great care ;

differences between two points may appear to be significant in one experiment and insignificant in a replication. Much of the hypothesis concerning the action of *CB* 1506 is based on a difference between eight lethals in the third brood and two in the fourth[7], a difference which by chance would occur once in about twenty experiments, and which on application of Yates's correction for small numbers becomes insignificant. The same paper[7] presents data from a second experiment with *CB* 1506, carried out on twice the scale with two-thirds the dose. Here the difference between mutation-rates in the third and fourth broods is wholly negligible (χ^2 less than 1). It seems risky indeed to erect a speculative building on such a shaky foundation. It is true that meanwhile Purdom[8] has published two or more brood pattern curves for *CB* 1506 which resemble the one presented by Drs. Fahmy[1] in their main features, although not in detail. In particular, both these curves show a slight and statistically insignificant drop ($\chi^2 = 1 \cdot 4$ and $0 \cdot 5$) from the third to the fourth brood. It is thus possible that such a drop, which rarely seems to reach the level of statistical significance, is indeed a feature of the brood pattern produced by *CB* 1506.

Since Purdom's data are not used by Drs. Fahmy[1], they are, however, not relevant to my criticism, which is directed against the *methods* of Drs. Fahmy, not against the possibility that some of their very insecurely based conclusions may, on further experimentation, turn out to have been inspired guesses. While, in my opinion, the interpretation of the brood pattern for *CB* 1506 gives too much weight to a scarcely significant difference, the opposite error may have been committed in regard to ethyl methane sulphonate. Here the drop in mutation frequency from the first to the second brood (ref. 1, curve *A*, Fig. 1) is disregarded as statistically not significant; but it might well be significant in repeated experiments. This would bring ethyl methane sulphonate into line with diepoxybutane for which, on the basis of one experiment, such a drop has been claimed as a distinguishing feature, and with triethylene melamine, for which a similar drop seems highly characteristic[5].

(*e*) The application of statistical methods to frequencies of visible mutations is even more misleading, because of the large personal factor involved in the scoring of these mutations. That even Drs. Fahmy are open to this criticism is illustrated strikingly by the fact that no visible mutations were reported among more than a hundred mutations in the first experiments with phenyl alanine mustard[10], a substance which afterwards has been stated to have "an extraordinary efficiency in the induction of visible point mutations", yielding regularly a ratio of three visible to ten lethal sex-linked mutations[11,12].

If one nevertheless insists on the use of statistical methods for experiments on visible mutations, account will have to be taken of heterogeneities within the samples to be compared. This has not been done for the noticeable—and statistically significant—drop in the ratio of visible to lethal mutations from the first to the fourth brood after the treatments listed in Table 1 (ref. 1). Moreover, the vast majority of mutations which have been produced by *CB* 1506 occur in germ cells which do not respond to the action of the other sulphonates; comparisons involving *CB* 1506 and one of these other substances are therefore comparisons not only of different mutagens, but also of different cell types. The importance of this distinction has recently been emphasized by Purdom[8], whose results show the important part played by germinal selection in influencing the relative frequencies of sex-linked visible and lethal mutations, when these are recovered from different stages of spermatogenesis.

(*f*) Drs. Fahmy[12] attribute the alleged differences in the visible/lethal ratios after different chemical treatments to the fact that certain 'morphogenesis loci' react specifically to certain chemicals. From a biological point of view this is exceedingly difficult to believe. The classification of mutations into visible and lethal ones is convenient, but it is neither strict nor biologically very meaningful. Every mutation is a visible one, if it is studied at the right time and by the right method. The only distinction is that lethals affect and kill the animal before emergence from the pupa, whereas 'visibles' affect the adult flies and often kill a proportion of them after or even before emergence.

(*g*) The speculations on the action of *CB* 1506 are open to the following objections: (1) The experimental basis is very slender (see above). (2) To postulate two different mutagens acting in series on two selectively sensitive stages is an uncalled-for complication. (3) In view of the known mutagenic activity of chloroethyl radicals, it seems unnecessary to postulate the formation of a chloroethyl amino-acid compound. In any event, the outcome of the proposed experiment with chloroethyl cysteine would be decisive only with very special assumptions which will be more fully discussed in *Z.i.A.V.*[3]. (4) Biological factors, such as differential penetration, selection, differences in rate and quality of metabolism, are wholly neglected. Experiments by Miss E. M. Sonbati and myself indicate that some of them influence the mutagenic action of *CB* 1506. (5) For reasons of scientific economy, the chosen interpretation of the brood pattern of *CB* 1506 should be adaptable also to an unrelated substance, 2-3-*bis*-ethylene amino-benzoquinone-1.4, which gives a similar brood pattern[13].

In the study of chemical mutagenesis on *Drosophila*, quantitative consistency of genetic response largely depends on the method of administration of the compound under test. The indirect methods of administration, especially that of mixing the compound with the food of the larvæ, result in complete lack of mutagenic consistency both in relation to the dose effect and the brood-mutation pattern[1]. This is perhaps what led Auerbach[2] to contest the possible achievement of reasonable consistency of brood-mutation patterns with the direct method of administration of the mutagens as developed in our laboratory.

(1) *The injection technique and mutagenic consistency.* With our method, accurately measured volumes of a solution of the compound are injected (by a micrometer-syringe) directly around the testes of males of the same age and average weight. In these circumstances, it has been shown[3-5] that for some compounds there is a fairly accurate and consistent relationship between the physical dose injected and the mutation-rate recovered. When the fractionation of the progeny of the treated males is undertaken at the same set periods, reasonable consistency of the brood-mutation pattern does occur, particularly within narrow dose-ranges. This has now been repeatedly ascertained for several alkylating compounds (unpublished) and is quite obvious from the published data, especially with the alkyl-methanesulphonates. The two experiments with 2-chloroethyl methanesulphonate[6], as well as a third undertaken by the same method and in our laboratory by Purdom[7], are clearly very similar; also those for methyl methanesulphonate[8] are almost diagrammatically identical. More extensive and comparable data with the above and related compounds are available, but obviously could not be included in the brief notes so far published.

The conclusion that with our standard brood technique spermatogonia differentiate into mature sperm within *roughly* 15 days is based on more than one line of evidence. We have already referred to the histo-genetic results with 2 : 4 : 6-tri(ethyleneimino)-1 : 3 : 5-triazine[4], which showed that pre-meiotic germ cells (spermatocytes and spermatogonia) give sperm which is utilized starting from the fifth brood, 13–15 days after treatment. That this timing applies equally well to 2-chloroethyl methanesulphonate is indicated by the appearance of 'visible' clusters in the fifth brood. Furthermore, the 'N-mustard' derivatives of amino-acids induce mutations at fairly high rates in all stages of spermatogenesis. In several of our recent experiments with these compounds, 'visible' clusters first appeared in the fifth brood. We feel justified in concluding, therefore, that under our experimental conditions, sperm *mainly* derived from spermatogonia is utilized in the fifth brood (within 15 days), irrespective of the treatment. This possibly means that under mild doses of the alkylating agents, the speed of germ-line differentiation is not drastically disturbed.

(2) *The brood-mutation curve and chemical reactivity.* Auerbach[2] emphasizes the lack of statistical significance for the drop in mutation-rate from the third to the fourth brood under the effect of the lower dose of 2-chloroethyl methanesulphonate[6]. This, however, is not essential to the hypothesis[8] we were expounding, namely, whether the rise in mutation-rate as a function of time after treatment (due to the possible retention of a slow-reacting compound) does continue after the third brood. The regression coefficients of mutations on broods (over the first three broods) for the two experiments (Table 1, ref. 6) did not differ significantly from each other. A conjoint coefficient was, therefore, calculated which indicated an increase in lethal percentage of 1·68 each brood. On this basis, the expected mutation-rate at the fourth brood for the lower dose would be 5·1 per cent, as compared to the observed 2·3 per cent (for the sample of chromosomes tested, $\chi^2 = 8{\cdot}3$, deg. freedom = 1, $P = 0{\cdot}006$). This clearly indicates that the mutation-rate observed in the sperm of the fourth brood is *very significantly* lower than expected on the hypothesis that the cells from which it is recovered have received a longer time of treatment than those utilized in the third brood. As postulated[8], this is probably due to the destruction of the 'residual' chloroethyl ester by hydrolysis (and other physiological factors) within less than the period of four broods (less than 12 days). It follows, therefore, that the much higher mutation-rate in spermatogonia which are utilized later than the fourth brood cannot be a function of time. Supporting evidence comes from the results with the fluoroethyl ester[8], which also possesses a slow-reacting methanesulphonoxy group and yet it does *not* induce a high mutation-rate in spermatogonia.

(3) *'Visible' mutations.* Auerbach[2] interpreted the lack of reference to 'visibles' in our preliminary reports on the 'N-mustard' derivatives of phenylalanine as evidence that none of these mutations was observed. Actually, the ratio of visibles to lethals in *all* our experiments with this mustard was of the order of 3 : 10. In the interim reports she referred to, only the lethal rates were given, and nothing whatever was said about the 'visibles'.

The statement[2] as to the heterogeneity of the ratio of visibles to lethals in the separate broods with the treatments listed in Table 1 of ref. 8 is rather ambiguous, since these data belong to two different compounds. A contingency table test for the relative frequency of these mutations in broods 1–4 gave for the ethyl ester $\chi^2 = 1{\cdot}8$, deg. freedom = 3, $P = 0{\cdot}6$, and for the methyl ester $\chi^2 = 7{\cdot}05$, deg. freedom = 3, $P = 0{\cdot}07$, thus revealing no pronounced heterogeneity.

Auerbach[2] raises the question of the possible role of cell-stage and germinal selection on the ratio of visibles to lethals recovered from various germ cells. This point will be dealt with in detail in a future publication. Suffice to say, however, that for all the alkylating mutagens tested in our laboratory, the ratio of sex-linked visibles to lethals for the same compound does not differ significantly for the separate broods up to and including the sixth. This ratio, however, was sometimes disturbed in favour of the visibles (presumably by differential germinal selection against the lethals) for mutations induced in the *very early* spermatogonia, which are recovered in the seventh brood (19–21 days after treatment). These mutations, however, did not contribute sufficiently to the total mutation pool in any of our experiments to alter significantly the overall ratio characteristic of the various compounds.

The exact biological mechanisms responsible for the variation in the ratio of visibles to lethals under the effect of different mutagens is at present entirely unknown and is one of the problems receiving attention in our laboratory. It may be a manifestation of various degrees of damage to the same loci; but might well be due to selective action on different loci. The merits of each of these views will be dealt with elsewhere, but whichever view is preferred can scarcely affect our conclusion: that if mutagens induce different ratios of visibles to lethals in the same sample of treated chromosomes, their mode of mutagenic action is somehow different.

(4) *Mode of mutagenic action of 2-chloroethyl methanesulphonate.* Our interpretation[8] of the mode of mutagenic action of 2-chloroethyl methanesulphonate is based on the comparative study of the chemical reactivity and mutagenicity of the above compound and some closely related alkyl-methanesulphonates. The mutagenic criteria considered were gross trends and points of detail were only mentioned as complementary evidence. Our argument rests on the complete reversal of the mutagenic cell-stage response under the effect of 2-chloroethyl methanesulphonate as compared with that of other alkyl methanesulphonates including the ethyl ester (see Fig. 2, ref. 8). As clearly stated in our contribution[8], and has been shown experimentally[9], changes in the brood-mutation pattern do occur with some compounds, due to cells being killed by the treatment, variation in the speed of differentiation of the germline, or on altering the experimental procedure, particularly the brood period. These changes, however, are of a much lower order than the gross difference that differentiates the mutation pattern of the chloroethyl ester from that of other alkyl-methanesulphonates.

Auerbach[2] suggests that the differential mutagenicity of the chloroethyl ester may be a function of the chloroethyl group which, she maintains, is known to be mutagenic. However, the fact that the chloroethyl group in 'mustards' (S- and N-mustards) is mutagenic does not mean that it is always so, irrespective of the configuration of the rest of the molecule. The biological activity of the chloroethyl group in 'N-mustards' has been shown by Ross[10] to be due to the tendency of these compounds to produce 'electrophilic' carbonium ions which would be expected to react with the 'nucleophilic' centres in the cell—particularly those of nucleic acids. Ross also demonstrated that the above tendency could be measured *in vitro* by the rate of hydrolysis of the chlorine atom under mild conditions. Since with 2-chloroethyl methanesulphonate, the chlorine atom does not hydrolyse in water at 37° C., whereas the methanesulphonoxy group does, there can scarcely be any doubt that the potential alkylating ability of the chloroethyl ester initially starts at the methanesulphonoxy end, as is the case with the other alkyl-methanesulphonates. If, however, the product of the initial reaction could be such as to 'activate' the chlorine atom of the chloroethyl group, then another alkylating centre would have been secondarily produced. Hence the search for the secondary agent that could account for the atypical mutagenic properties of the chloroethyl ester.

As clearly admitted in our article[8], the suggested formation of a secondary mutagen under the effect of 2-chloroethyl methanesulphonate was only inferential, and our idea about its chemical nature was purely speculative, but experiments were designed for testing our hypotheses. The first series of experiments using S-chloroethyl cysteine (one of the possible metabolites) has now been undertaken. The brood-mutation pattern for this compound was found to be of essentially the same type as that for 2-chloroethyl methanesulphonate, though indicating far greater selectivity for the early germ cells (details to be published elsewhere). An injected concentration of S-chloroethyl cysteine as low as $0{\cdot}4 \times 10^{-3}$ molar induces a sex-linked recessive lethal-rate of 30 per cent in the most sensitive spermatogonia as compared to a maximum of only 1·6 per cent among the sperm and spermatid stages. Other amino-acid mustards that are likely to be produced *in vivo* through the effect of the chloroethyl ester (particularly in conjunction with cysteine metabolism) will be tested for mutagenicity. However, the results with S-chloroethyl cysteine suggest that our reasoning as to the mode of mutagenic action of 2-chloroethyl methanesulphonate was on the correct lines: that the high response of spermatogonia under its effect is probably due to the production *in vivo* of a secondary mutagen other than the sulphonate itself.

THE editors of *Nature* have kindly given me leave to wind up this discussion with a few lines; they do not wish a continuation of technicalities, and I refer, therefore, for details of my criticism to my paper in *Z.i.A.V.* Here I only want to say this: although the reply by Drs. Fahmy seems to meet all my objections, it does in fact, on closer analysis, confirm that their methods and reasoning were, point for point, exactly as stated and criticized by me. Their reply contains no new references to published data; their insistence on the repeatability, in their experiments, of the relation between dose and effect is wholly irrelevant to the argument; the calculation in section 2 is based on too specious an argument to be taken seriously; finally, it is very difficult to understand why "an extraordinary efficiency in the production of visible mutations" by certain compounds should have been noted but not mentioned for a full year during which two lengthy interim reports came out, especially as this result was first made public in exactly the same kind of interim report. If the speculations on the action of *CB* 1506 have led to the discovery of a further interesting mutagen, they certainly have had heuristic value. It does not follow, however, that they were correct or even well founded. Two substances may well produce similar brood patterns without one being a metabolic descendant of the other (see the last section of my communication above). Moreover, it would not be the first time that an effective mutagen has been detected on the basis of a wrong or doubtful hypothesis.

X-Ray Study of Laboratory-made Diamonds

LAST summer one of us was able, through the courtesy of the General Electric Co., of Schenectady, New York, to select a few of the diamonds made in the Company's Research Laboratories and to bring them to University College, London, for detailed X-ray examinations. These diamonds are mostly very small (less than ½ mm. linear) and are coloured (yellow, green, black) and good shapes are rare. Although some colourless diamonds have been made, there were none among our collection, nor did we have any of those of pure cubic form. The habits, which are exceedingly interesting, will be discussed in the more extended account of this work to be published later.

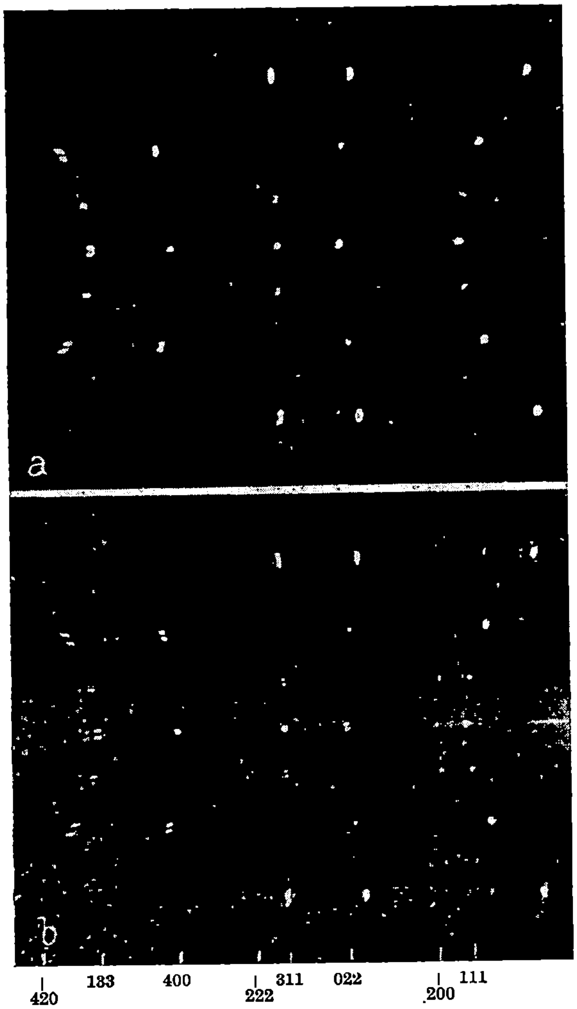

Fig. 1. (*a*) Twinned natural diamond. Rotation slightly mis-set from [01$\bar{1}$] for one individual: showing 111, 022, 311, 222 (very weak) 400, 133 reflexions. Copper *K* radiation, filtered. (*b*) Twinned laboratory-made diamond: same setting and radiation; showing, in addition to the above, the 'forbidden' 200 (medium) and 420 (very weak) reflexions, with very weak satellites to all others. Only the 200 spots are clearly visible on the reproduction

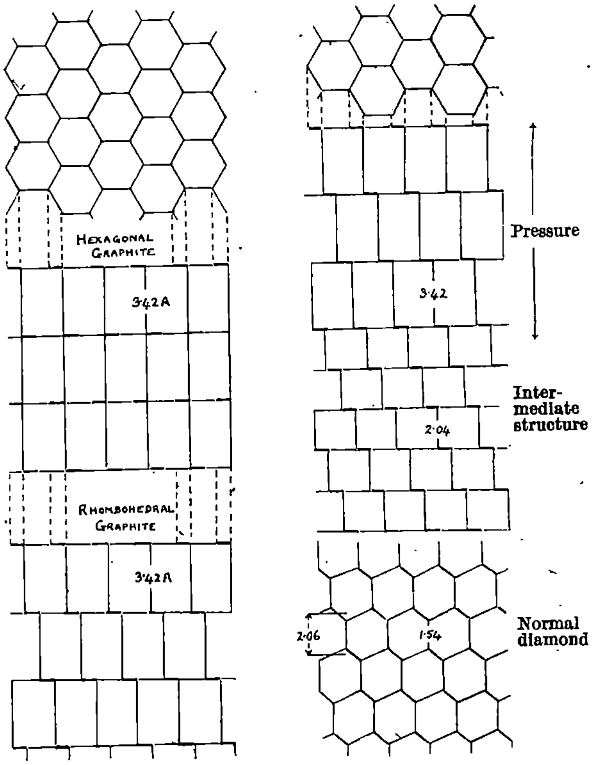

Fig. 2

Ten representative specimens have been studied so far. Laue photographs show that only two crystals are comparatively single and free from distortion; but five have given, using chromium, nickel, copper and molybdenum radiations, good rotation and/or Weissenberg photographs (about [001] and [01$\bar{1}$]) on which it is easy to distinguish spots due to the main specimen from those of its associated twin. In every case these laboratory-made diamonds show one outstanding diffraction feature, namely, the presence of a comparatively strong 200 reflexion, which is never shown by any natural diamond, whether of terrestrial or meteoritic origin, that we have studied. There are other 'forbidden' reflexions (h, k, l even and $h + k + l = 4n + 2$) present also, and nearly all the normal diamond reflexions show a faint satellite on the short-spacing side (Fig. 1).

All the low-order reflexions are sharp, but the 'forbidden' and 'satellite' spots are sometimes a little extended along arcs with θ constant, showing that they are given by a mosaic or conglomerate of slightly disorientated crystallites.

The explanation of the diffraction phenomena appears to be as follows. Each diamond consists of a matrix of normal diamond, of lattice constant 3·567 A., with carbon atoms at the usual positions:

$$000,\ 0\tfrac{1}{2}\tfrac{1}{2},\ \tfrac{1}{2}0\tfrac{1}{2},\ \tfrac{1}{2}\tfrac{1}{2}0\ +\ |000,\ \tfrac{1}{4}\tfrac{1}{4}\tfrac{1}{4}|$$

in each unit cell. Within this matrix there are islands of a different structure which is face-centred cubic with lattice constant 3·54 A. These islands lie closely parallel with the diamond matrix and must be at least 10,000 A. across to account for the sharpness of the reflexions, although some broadening of the 331 and 420 indicates possible distortion or strain.

A spectroscopic analysis of the diamonds, carried out in Messrs. Johnson Matthey's Research Laboratories, demonstrates the presence of some 0·2 per cent of nickel, with smaller quantities of other elements (Si, Al, Fe, Mn, Mg, Na, K, Ti, Ca, Cr, Cu, B). This points to a probable explanation of the subsidiary structure. β-Nickel has a face-centred cubic structure of lattice constant 3·52 A.; nickel carbide, a solid solution Ni_xC where $x \geqslant 4$, is face-centred cubic above 210° C. and has[1] the slightly higher parameter 3·54 A. A simple face-centred cubic structure would not account for the high intensity of 200 relative to other lines in the satellite structure. The addition of some impurity or solvent atoms could do so. A calculation shows that for incident nickel, copper $K\alpha$ or molybdenum radiation, even so small an amount of nickel as 0·2 per cent, concentrated in a few well-crystallized and parallel islands, would give reflexions of appreciable intensity, but that for chromium or copper $K\beta$ radiation they would be much reduced in intensity if the extent of each island is more than some 4×10^{-4} cm. linear. This reduction in intensity is found to occur.

Nickel does not normally appear as an impurity in natural diamonds. The closeness of its lattice constant to that of diamond would point to it, however, as a possible inducer of crystallization of carbon in the diamond form (much as β silver iodide can induce the precipitation of ice in clouds). The process of cooling from high temperatures and simultaneously expanding from high pressures could well leave islands of face-centred cubic nickel or Ni_xC or some other nickel compound in a state of strain; and the existence of orientation relationships (not necessarily complete parallelism) in a precipitated phase is typical, for example, of Widmanstätten patterns in iron-rich nickel–iron alloys in diamond-bearing meteorites. The presence of nickel in these laboratory-made diamonds recalls the Press release (February 15, 1955) by the Research Laboratory of the General Electric Co., in which it was stated that its scientists had "gained valuable help from nature, particularly from studies of diamonds found in Arizona meteorites". This will be discussed in our later paper.

The question still remains as to the actual mechanism of transformation from graphitic carbon (assuming this to be the initial substance) to diamond. This could in fact occur via an intermediate carbon structure, as shown in Fig. 2. This structure, if it has carbon atoms in the positions ($x \sim \frac{1}{24}$)

$$000,\ 0\tfrac{1}{2}\tfrac{1}{2},\ \tfrac{1}{2}0\tfrac{1}{2},\ \tfrac{1}{2}\tfrac{1}{2}0 + |\ \bar{x}\bar{x}\bar{x};\ \tfrac{1}{4}+x,\ \tfrac{1}{4}+x,\ \tfrac{1}{4}+x\ |$$

in a unit cell which is geometrically cubic, of side 3·54 A., but of rhombohedral symmetry only, would give reflexions in precisely the positions of the satellite spots. Apart from the variation of absorption factor with incident radiation, the occurrence of such an intermediate structure, in islands, each with its trigonal axis orientated parallel to one of the four diamond octahedral directions, could scarcely be distinguished from that of the nickel-rich islands we have postulated as the main cause of the satellite reflexions.

Nath[2] suggested in 1935 that the reverse transformation, diamond → graphite, might take place via rhombohedral graphite, but no experimental evidence of this has yet been found, even in heavily irradiated or heat-treated diamonds[3]. We should also emphasize that even the blackest of the laboratory-made diamonds examined showed no trace whatever of the strong 0002 reflexion typical of both hexagonal and rhombohedral graphites, or any other purely graphitic reflexion.

We would like to express our thanks to members of the research staff of the General Electric Company, Schenectady, who, within the limitations of United States security regulations, have given us every assistance in this investigation.

Nuclear Quadrupole Resonance of Neutron-irradiated Sodium Chlorate

RECENTLY a method based on intensity measurements in pure quadrupole resonance has been developed and has proved itself useful for the study of solid solutions[1] and for the investigation of the damage induced in pure solid compounds by high-energy radiations such as gamma-rays[2].

The present work was undertaken in order to try to extend this method to the case of neutrons. With this in view, fused samples of sodium chlorate, which presents a favourable signal-to-noise ratio, were irradiated at 95° C. in the Belgian *BR*–1 reactor in which a high ratio of neutron to gamma energy is provided. A frequency-modulated super-regenerative detector was used and the spectra were automatically recorded after phase-sensitive detection of the signals.

The observations performed at 23° C. showed that the height of the line (located at 29·932 Mc./sec.) corresponding to chlorine-35 was decreased by about 25, 36 and 52 per cent for irradiations with doses of 2×10^{14}, 10^{15} and 2×10^{15} fast neutrons cm.$^{-2}$, respectively. We were unable to detect any significant shift in the line frequency and, as was found to occur with the gamma-rays[2], a plot of $\log I$ (irradiated sample) $-\log I_0$ (unirradiated sample) versus the dose gave a straight line. This shows that, despite a different type of effect, an exponential law still describes the intensity behaviour. It should be noticed that, within the range of doses used, no significant broadening of the line (measured by the separation between the peaks of the first derivative curve) was observed. For this reason, the intensity of the line was regarded as being satisfactorily represented by its height.

It may now be stated that the method here reported is also valuable for the study of damage induced by neutrons. Further research, including radio-resistance in terms of structure and recovery effects, is now in progress.

We are indebted to the Centre d'Etudes pour les applications de l'Energie Nucléaire for irradiation facilities.

Flame Ionization Detector for Gas Chromatography

IT has been found that the electrical conductivity of a flame burning a mixture of hydrogen and nitrogen (in air) is very sensitively affected by the vapours of organic substances, and this effect can be used for detection purposes in gas chromatography.

In a simple form of the detector the carrier gas used was a mixture of approximately equal parts by volume of hydrogen and nitrogen and the issuing gas was burnt at a jet made from a 23-gauge hypodermic needle (cut square) which itself served as the positive pole for the conductance measurement. The negative pole consisted of a piece of 30-mesh brass gauze, about 1 cm. above the needle, and the current, driven by a battery of about 300 volts, passed through a 100,000-ohm resistor, across which a Leeds and Northrup 10-mV. potentiometric recorder was connected. The sensitivity of this arrangement to organic vapours was at least as good as reported for the best katharometers.

For the highest sensitivity yet obtained, a double triode 'long-tailed pair' impedance conversion circuit was used (voltage gain about × 2), with a reference jet (burning the same gas mixture) feeding one grid and the detection jet feeding the other. Circuit details are shown in Fig. 1.

The valve is an *E80CC* (Philips), heaters in series with a 12-volt accumulator. The output is filtered with an *RC* circuit with a time constant of about 5 sec. The combustion chamber and collector leads are completely shielded. The combustion chamber is supplied with filtered air since dust particles cause large disturbances.

With the jets connected to short partition columns, injection of 0·01 ml. of a solution of one part of diethyl ether in 10,000,000 of ethyl acetate (by liquid volume) gave an output of about 1 mV. for the ether peak, which was eluted during the passage of 100 ml. of carrier gas. This deflexion was about five times the background fluctuations, and the sensitivity (for twice background) was estimated at not less than 5×10^{-12} mole of diethyl ether, or 4×10^{-10} gm. The sensitivity at the point of detection was about one part in 400 million (by gas volume). From the daily variations in background, it is thought probable that the sensitivity is at present limited by the quality of the insulation and the stability of the grid resistors rather than by the stability of the flame outputs. (Much higher output could be obtained with higher grid resistances, provided background was not proportional.)

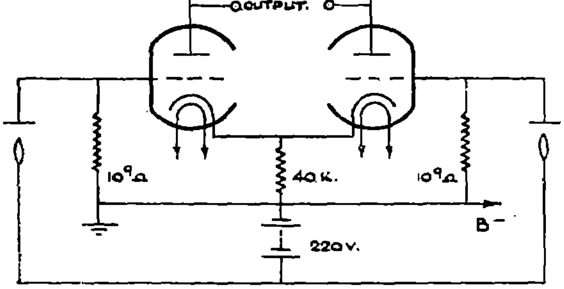

Fig. 1. Circuit of dual-jet detector

With the double-jet system fed with the same gas mixture to both columns, the base line is remarkably insensitive to nitrogen–hydrogen ratio, total flow-rate, vibration, ambient temperature or minor variations in the supply of filtered air. The air supply is passed straight into the bottom of the jet chamber without any device to suppress turbulence.

Other organic vapours so far tried give sensitive responses, including benzene, toluene, xylene, carbon tetrachloride and methylene chloride. Very little if any response is obtained with carbon dioxide.

Preliminary measurements and calculations based on Faraday's law, appear to indicate an ion yield of between one and ten ions per 10,000 molecules of ether, but further investigations, using electrometer valves with very low grid currents, are planned. It is hoped to publish the results at a later date.

A remarkable demonstration of the sensitivity of the apparatus (and of the difficulty of producing known concentrations of vapour by serial dilution) is given by charging an ordinary 2 ml. glass hypodermic syringe with ether vapour, pumping out completely about 100 times, and then injecting a syringeful of air. A peak of several millivolts is obtained, from ether desorbed from the glass.

The above detector was described at a discussion on gas chromatography held at Cambridge on October 4, 1957.

We thank Imperial Chemical Industries of Australia and New Zealand for permission to publish this communication, L. E. Polak, S. Lattimore and F. A. Walter for invaluable advice on the electronics, and V. E. Maier and W. J. Bryant for able assistance.

Polarization of the Integrated Light of Comet Arend-Roland, 1956*h*

FROM a pair of photographs of the comet taken on the night of April 29–30, 1957, through a 'Polaroid' filter with the 50-cm. Zeiss triplet of the Mond Astrograph, percentage polarization in integrated light (spectral range, 4000–5900 A.) has been measured in the brightest part of the coma, and also at two locations in the tail 4 and 5 min. of arc respectively from the former position. The small scale of the photographs (6·85 min. of arc/mm.) prevented any attempt at a more detailed survey.

The correct position angle of the polarizing filter was determined visually by a preliminary observation of the comet, and the filter was rotated through 90° between the successive exposures, which were given separately on Kodak *O* 800 plates. It had been intended to give an exposure time of 2 hr. in each instance; but the presence of clouds limited the exposure through the 'crossed' filter to 1 hr. 20 min. The mean altitude of the comet was approximately 20°.

Both plates were microphotometered; and the photographic density measures at each of the three selected locations were reduced by the aid of magnitude–density curves, based on measurements of the trailed images of five field stars, namely, *H D*, 21291, 21389, 21447, 25291 and 25642. No corrections were applied to the observed magnitudes for differential atmospheric extinction.

The following values of percentage polarization were obtained: in the brightest part of the coma, 41 ± 5 per cent; in the inner tail, at a point 4 min. of arc from the coma, 51 ± 5 per cent, and at a point 5 min. of arc distant, 35 per cent, with the plane of polarization along the radius vector to the Sun.

Because of under-exposure, the total density in the image of the tail recorded through the 'crossed' analyser equalled the threshold (sky background) value at an angular distance of only 7 min. of arc from the bright, central region of the coma. Thus the probable error of the third measurement given above is uncertain and, in consequence, this result should have less weight than the other two.

The amount of polarization found in the head of the comet agrees well with the value of 45 per cent obtained on an unspecified date by Richter[1], who also used a polarizing filter. However, it is nearly 20 per cent higher than the maximum polarization found by Blackwell and Willstrop[2] in the continuous spectrum of the comet.

Richter (*loc cit.*) has reported that the comet's tail was also 45 per cent polarized out to a distance of 4° from the head. The present results suggest that this value may even be exceeded at the base of the tail near its junction with the coma.

The α-β Transformation in Keratin

THE possibility of obtaining from X-ray diffraction results a quantitative estimate of the course of the α–β transformation as a keratin specimen is stretched is so important that attempts such as that of Bendit[1] are to be welcomed. I feel, however, that it is impossible to say the same about the proposal recently put forward by V. D. Gupta[2], who measures for specimens at various extensions the value of an index

$$\Omega = \frac{I_e - I_m}{I_e + I_m} \times 100$$

which he wishes to take as a measure of what he calls the "degree of order". So far as can be gathered from his somewhat ambiguous phraseology, the quantities I_m and I_e are the intensities of the meridional and equatorial diffraction spots, the former the group of reflexions with spacings near 5·1 A., and the latter the reflexions with spacings near 10 A. (common to the α- and β-photographs) and near 4·65 A. (characteristic of the β-photograph). If this interpretation of Gupta's intentions is correct, then changes in Ω are indications not so much of changes in the degree of order (whatever this might mean) as of changes in the β : α ratio. His conclusion that during stretching there is an initial rapid rise in the degree of order, with little further change at extensions greater than 40 per cent, should therefore be replaced by the almost trivial result (it was not so trivial 30 years ago) that the X-ray photograph at 40 per cent extension is more like that at 70 per cent extension than it is like that of unstretched fibres.

To talk about "degree of order" in a material like keratin, with its potentialities for changes of crystal structure, state of crystallite orientation, and crystallinity ratio, without making it quite clear whether some or all of these or some other unspecified characteristic of the material is involved, is, we consider, dangerous and misleading. If, for example, we agree to measure lack of order by the entropy, experiments on the elastic properties[3] indicate that in the initial stages of extension there is a *decrease* in the degree of order; I think that this is confirmed when the results of X-ray diffraction experiments are properly interpreted.

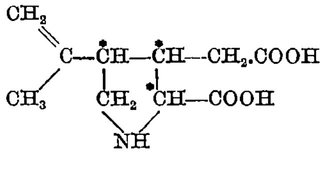
Structure of Kainic Acid and its Isomer, Allokainic Acid

IN 1953, Murakami, Takemoto and their collaborators[1] isolated the most active component of *Digenea simplex* Agardh which has been well known as an anthelmintic (vermifuge) for more than a thousand years. They named it kainic acid after 'Kaininso', the Japanese name of the mother alga. Kainic acid, $C_{10}H_{15}O_4N$, has an intense anthelmintic effect, about ten times that of santonin, without side-effects. In conjunction with chemical studies[2] to determine the structure of this interesting compound, we have carried out a structural determination by means of X-ray crystal analysis.

Following orthodox X-ray procedure the research was commenced with a salt containing zinc as a heavy atom. Zinc kainate crystallizes with two molecules of water in colourless prisms, which are orthorhombic. The space group was found to be $P2_12_12_1$, and the dimensions of the unit cell, containing four units of $C_{10}H_{13}O_4N$ Zn.2H_2O, were as follows: $a = 25·50$, $b = 6·93$, $c = 7·60$ A. By the trial-and-error method based on the presence of the heavy atom, electron-density projections along the *b*- and *c*-axes were derived, and the structure of kainic acid was found to be 2-carboxyl-3-carboxymethyl-4-*iso*propenylpyrrolidine, with the stereoconfiguration shown in the structural formula (asymmetric centres are marked by asterisks):



The structure of the molecule in the zinc salt is illustrated schematically in Fig. 1, where it is viewed along the *b*-axis.

In addition, we examined kainic acid itself. From water, kainic acid crystallizes with one water molecule, in colourless needles which are monoclinic. The dimensions of the unit cell were as follows: $a = 12·07$, $b = 5·86$, $c = 8·19$ A., $\beta = 94·7°$. The space group was $P2_1$, and the unit cell contained two units of $C_{10}H_{15}O_4N.H_2O$. By trial-and-error methods the electron-density projections along the three principal crystal axes were obtained, and the result was in

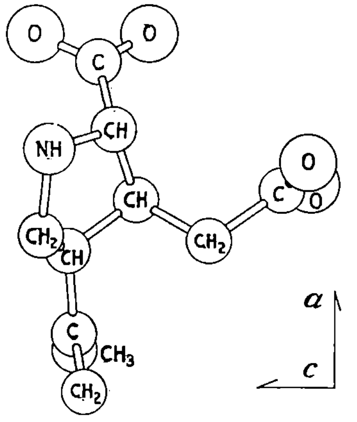


Fig. 1. The structure of the kainate anion

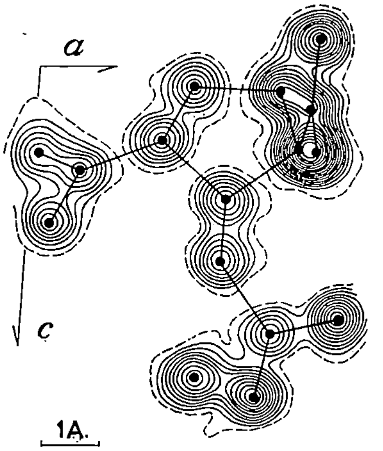

Fig. 2. The electron density of kainic acid monohydrate, projected on (010)

agreement with that for the zinc salt. The *b*-axis electron-density projection is shown in Fig. 2.

Furthermore, we analysed an isomer of kainic acid, allokainic acid, which is found also in *Digenea simplex* Agardh. It is weakly anthelmintic, if at all. Crystalline allokainic acid forms colourless prisms with no water of crystallization; the space group is $P2_12_12_1$, and the four units of $C_{10}H_{15}O_4N$ are contained in a cell of dimensions: $a = 26 \cdot 08$, $b = 5 \cdot 83$, $c = 6 \cdot 95$ A. The electron-density projections along the *b*- and *c*-axes were derived by the trial-and-error method. The stereochemical structure of the molecule is represented in Fig. 3, viewed along the *b*-axis. The structural relationship between the two isomers can be seen by comparison with Fig. 1. Accordingly, allokainic acid can be said to be a stereoisomer of kainic acid, differing merely in the configuration of one of its side-chains, namely, by reversal of the configuration at C_4 of the pyrrolidine ring. It is of interest that the anthelmintic effects of the two isomers are remarkably different from each other, due, apparently, to the dissimilar configurations of the *iso*propenyl side-chain.

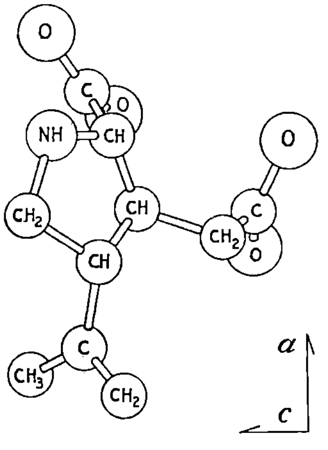

Fig. 3. The structure of allokainic acid

These X-ray results completely coincided with the conclusions[2] deduced from the chemical behaviour. This work will shortly be published in detail in the *Bulletin of the Chemical Society of Japan.*

Colour Filters for the 4358-A. Line of the Mercury Discharge Spectrum

In connexion with other work[1], experiments have been carried out with the aim of obtaining an improved filter for the 4358-A. line of the mercury discharge spectrum which is of interest for photochemical and spectroscopic investigations.

We have found that a solution filter consisting of 9 : 10-dibromoanthracene (or 9 : 10-dichloroanthracene) and of crystal violet perchlorate in suitable concentrations and solvents will separate the 4358-A. line with a transmission of 80 per cent almost completely from all other lines of the mercury discharge lamp, including that of the intense neighbouring 4047-A. line.

Table 1 shows transmission data for various concentrations and thicknesses in ethanol–toluene solution (measured against air, if not otherwise stated).

Probably the most suitable filter containing 0·0125 per cent crystal violet perchlorate and 0·02 per cent 9 : 10-dibromoanthracene has a transmission in a 1-cm. cell measured against air at the mercury lines of 5790 ($<10^{-10}$), 5461 ($<10^{-10}$), 4358 (81 per cent), and 4047 A. ($<10^{-4}$). Reflexion losses at 4358 A. represent an appreciable part of the transmission losses and are slightly greater if the solutions of the perchlorate and of dibromoanthracene are kept in separate cells. No precautions have been taken for their reduction. The pass-band (width of band at twice the intensity observed at 4358 A.) is 325 A. (against air) and 260 A. (against cell and solvent). This may be compared with the 42 and 1 per cent transmissions at 4358 and 4047 A., respectively, and with the pass-band of approximately 500 A. for the best copper salt/sodium nitrite filter suggested elsewhere[2] and the <5 per cent transmission at 4358 A. of the commercial filters available.

Table 1. TRANSMISSION DATA FOR FILTER CONTAINING CRYSTAL VIOLET PERCHLORATE AND 9 : 10-DIBROMOANTHRACENE IN ETHANOL AND TOLUENE

Crystal violet perchlorate (per cent)	9 : 10-Dibromoanthracene (per cent)	Solvent	Cell	Per cent transmission at λ, A.

* Measured against cell and solvent.

The light fastness of these filters has been investigated by exposure to the G.E.C., 400-W. Osram[3] and the very intense B.T.H., 240-W. Mazda lamp[4]. The cells containing the filters were sealed to prevent evaporation and to keep atmospheric oxidation to the minimum.

Table 2 shows the transmission changes of the filter in ethanol–toluene solution on irradiation in various conditions. The light fastness is particularly satisfactory when a sealed cell containing dibromoanthracene in toluene is placed in front of one containing crystal violet in ethanol.

Table 2. CHANGE IN TRANSMISSION ON IRRADIATION

Filter	Cell	λ, A.	Per cent transmission after exposure		
			(0)	Osram (20 hr.)	Mazda (6 hr.)
0·0125 per cent crystal violet and 0·02 per cent 9 : 10-dibromoanthracene in ethanol/toluene (1 : 1)	1 cm.	5790	0	0	0·2
		5461	0	0	2

Agar as Specimen Carrier in Double-Beam Infra-Red Spectroscopy

METHODS for preparing specimens for infra-red spectroscopy are limited. A workable addition to the few techniques available should extend the usefulness of infra-red spectroscopy.

Pollen polysaccharides prepared by the Bencard Allergy Research Unit gave films too brittle to be transferred from the base on which they were dried when prepared by the method of Orr[1,2]. To prepare them for infra-red spectroscopy one of us (J. G. F.) adapted a method previously reported for preparing films of antigen–antibody precipitation patterns in agar[3]. The polysaccharides were incorporated in an agar gel which was afterwards dried to a film. Films for spectroscopy have been made by others from gelatine[4], polystyrene[5] and polyethylene[6].

An approximately 0·8 per cent stock agar is made from 'Oxoid *L*.10', thoroughly clarified by a previously published method[7] and the gel dialysed by soaking in several changes of distilled water. This appears to remove a band of unreproducible intensity in the 4·9μ region. Material for infra-red examination is dissolved or suspended in distilled water in suitable concentration and mixed with an equal volume of melted stock agar cooled to about 56° C. 2 ml. of the agar-specimen mixture is pipetted on to a siliconed glass plate, for example, a lantern slide cover glass, and spread out to cover the area within a 1½-in. internal diameter metal or plastic ring. Simultaneously, a control film is prepared in the same way with distilled water.

The agar is allowed to gel, the gels are cut free of the rings with a sharp-pointed blade, the rings removed and the plates with the gel disks air-dried overnight at 37° C. The dried films are coherent and can be lifted from the siliconed glass surface for mounting in cell holders. A film may be cut to a desired size by placing a lead spacer or suitably sized disk on it and ringing with a pointed blade. Alternatively, they can be mounted on annular linen gummed reinforcements of suitable size, care being taken to avoid contaminating or straining the film.

When made with non-crystallizing substances, for example, polysaccharides, the films are clear and transparent. When crystallization occurs, for example, with glycine and urea, it does not hinder spectroscopic examination. Films have also been prepared from substances in suspension, such as micro-organisms.

Agar films (Fig. 1) were examined in the Grubb Parsons double-beam spectrometer. Adequate cancellation of the agar spectrum and uniformity of optical density, as checked by film rotation, can be obtained if the films are dried under the same conditions.

Differences in spectra associated with methods of preparation and presentation of samples are recognized occurrences. The spectra for substances in agar

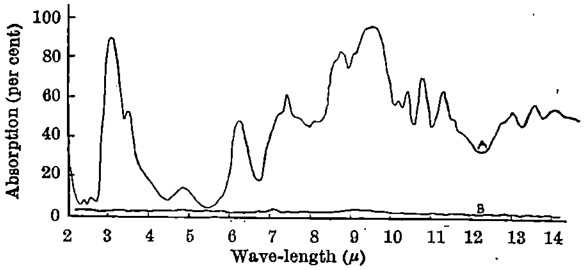

Fig. 1. Infra-red spectra of agar films. *A*, uncompensated single film ; *B*, difference spectrum of two films

films are characteristic of the method and reproducible, though differing in some details from those in potassium bromide disks (Fig. 2). Thus, in agar gel films the glucose spectrum loses some of its fine structure (also observed by Kuhn[8] in his vacuum-dried sugar preparations), and there is a reversal of the relative intensities of the $10 \cdot 9\mu$ and $11 \cdot 2\mu$ glycine bands.

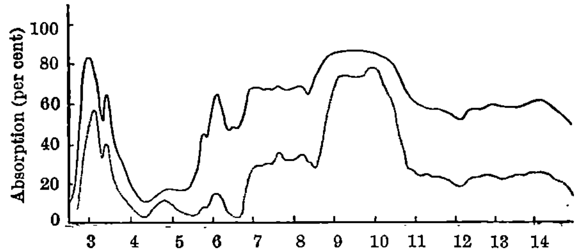

Fig. 2. Infra-red spectra of timothy grass pollen polysaccharide. · · · ·, agar films ; ——, potassium bromide disk

As the agar gel film technique is directly applicable to dissolved or suspended substances it may be particularly useful for process analysis and control.

No attempt has been made to control the water content of the films beyond the initial drying, but recent[9,10] observations on the effect of water content on infra-red spectra should be considered.

We wish to thank Mr. D. F. Lawson for photographing the spectra.

A Rotating Hanging Mercury-Drop Electrode

THE work of Gerischer[1] and Delahay *et al.*[2] suggested to us the use of the hanging mercury-drop electrode as a rotating electrode. This electrode, used as a stationary electrode (as proposed by Ross *et al.*[3]), offers several distinct advantages over the conventional dropping-mercury electrode. The charging current is largely reduced, the current-voltage curve can be scanned in a shorter time and the curve-distorting oscillations are eliminated. However, used as a rotating electrode its advantages are even greater. The electrode owes its greater sensitivity to the accelerated diffusion of reducible species (thinner diffusion layer). Peak-formation in the current-voltage curve is prevented, because depletion of the reducible species in the diffusion layer of the electrode cannot occur. If desired, the curve can be plotted manually : it resembles the polarogram in its ideal form. Analysis of multicomponent systems offers none of the extra difficulties encountered with the stationary type[3], and compensation of the diffusion current of a more noble metal ion, preceding the diffusion current of the metal ion to be determined, is therefore possible. The reproducibility of repeated determinations on the same solution is comparable to or better than that of conventional polarography. It is possible to determine concentrations of reducible ions as low as $10^{-7}\,M$.

Fig. 1 shows the cell and the rotating electrode. The saturated calomel electrode is connected to the cell by means of a salt bridge containing a 3 per cent agar gel, saturated with potassium chloride; the end of the bridge also functions as stopper.

The cell is thermostated at 25·0 ± 0·1° C. Nitrogen may be either bubbled through or passed over the solution (when recording) through stopcock *K*. Details of the electrode are also shown in Fig. 1 : the platinum wire (diameter, 0·5 mm. ; length, 0·5 mm.) projecting from the end of a soft-glass tube is thinly plated with gold. Two drops of the conventional dropping-mercury electrode type can readily be attached to the plated platinum electrode and adhere even when the electrode is rotated at a speed of 750 r.p.m., provided the tip of the electrode is on the axis of rotation. A constant speed of rotation is necessary to obtain a constant diffusion current. The hanging mercury-drop electrode can be reproduced easily if necessary.

An example of a current-voltage curve of a two-component system ($10^{-4}\,M$ Pb^{++} and $10^{-4}\,M$ Cd^{++}

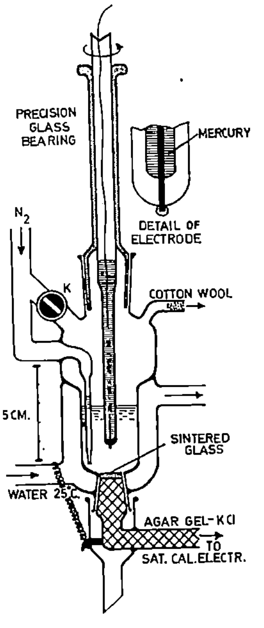

Fig. 1. Voltameter cell with detail of electrode

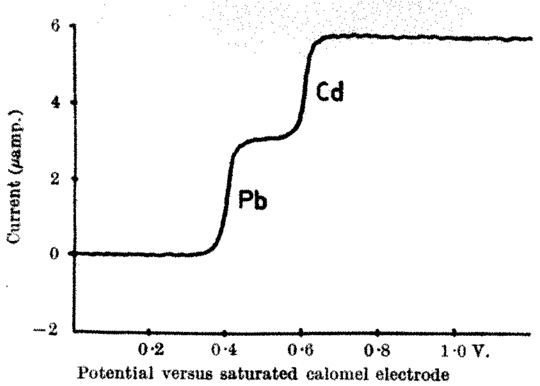

Fig. 2. Current-voltage curve of a two-component system (10^{-4} M Pb^{++} and 10^{-4} M Cd^{++} in 0·1 M potassium chloride at *c.* 500 r.p.m.)

in 0·1 *M* potassium chloride) is shown in Fig. 2. The voltage-scanning rate was equal to that commonly used in conventional polarography.

Further details of this electrode, which appears to be a useful analytical tool, will be published elsewhere. Since this communication was written, our attention has been directed to recent work by Delahay *et al.*[4] in which he used a rotating electrode in voltameter studies of anodic stripping.

Detection of Triterpenoid Acids on Paper Chromatograms

In the course of an investigation of triterpene acids from natural sources it was necessary to devise tests for the detection of these compounds on alumina-impregnated filter paper.

A very convenient method is to spray the filter paper with a solution of phosphotungstic acid. Noller's reaction[1] has been used for the detection of triterpenoid compounds on filter paper; the Neher and Wettstein test[2] is also suitable for this. After spraying the paper chromatogram of triterpene acids with a solution of goat's blood[3], hæmolysis was observed.

The procedure is as follows. The paper chromatogram after development with the solvent is thoroughly dried by a current of hot air. It is next sprayed with a 25 per cent solution of alcoholic phosphotungstic acid and dried carefully for 2 min. in an oven kept at about 115–118° C. The paper then showed well-defined coloured spots against a white background; 3–5 μgm. of each component acid could be detected on the chromatogram.

Table 1. Colours of Spot Tests for Triterpene Acids

Substance	Alcoholic phosphotungstic acid (25 per cent)	Stannic chloride in thionyl chloride (1 per cent)	Zinc chloride in benzoyl chloride
Poliporenic acid *A*	Orange	Orange	Blue-purple
Glycyrrhetinic acid	Yellow-brown	Yellow-brown	Yellow-brown
Ursolic acid I	Pink-purple	Pink→violet	Pink→violet→blue
Betulinic acid	Brown-violet	Yellow-violet	Yellow-brown
Oleanolic acid	Pink-purple	Pink→violet→blue	Pink→violet→blue

The demonstration of triterpene acids on a paper chromatogram is also possible after treatment by the modified Noller reaction. Quantities of triterpene acids of about 5 μgm. on paper can be detected successfully after drawing the strip through a solution of 1 per cent anhydrous stannic chloride in pure thionyl chloride and heating it for 60–80 sec. at 85–90° C. Spots of different colours are obtained with the triterpene acids.

For the hæmolysis test, a solution of defibrined goat's blood in normal saline (1 : 8) is used. After spraying, the triterpene acids appeared as lighter spots on a tan background. In some cases, the spots become more distinct after the paper has dried and occasionally they were more readily discernible in transmitted light.

For the detection of triterpene acids on alumina-impregnated filter paper Gross's[4] and Belic's[5] reagents can be used. However, these reactions are not so useful in practice. Full details of this work will be published in *Chemia Analityczna* (Poland).

Qualitative, Quantitative and Preparative Chromatography of Steroids on Fully Acetylated Paper

The majority of methods developed for the paper chromatographic separation of steroids involve impregnation of the paper with a relatively polar, non-volatile liquid, such as propylene glycol, formamide or 'Phenylcellosolve', a less polar liquid being used as the mobile phase. Some 'reversed phase' techniques have also been applied, in which the paper is rendered hydrophobic by impregnation with 'Quilon', paraffin oil, kerosene or silicone and the mobile phase is a relatively polar liquid. Impregnation of the paper is usually difficult to carry out in a reproducible way and therefore R_F values may depend on slight experimental variations. Moreover, impregnation with a non-volatile liquid may interfere in quantitative determinations.

Chromatography on acetylated paper has the advantage of requiring no such impregnation. The separation of various substances on partially acetylated paper has been described by several authors[1]. It is, however, difficult to obtain a homogeneous

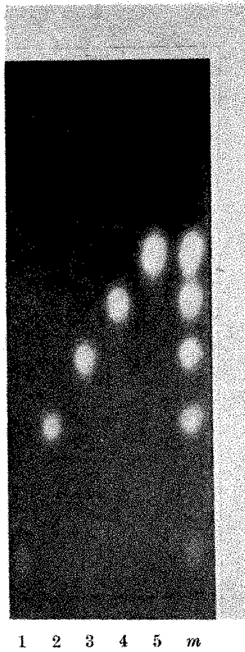

Fig. 1. Method *B*

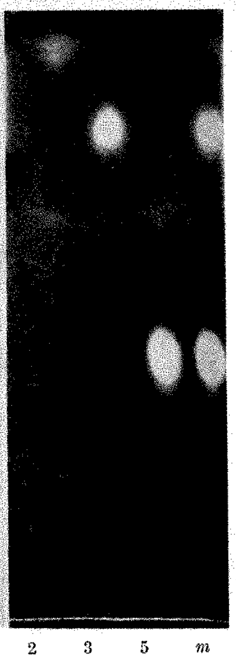

Fig. 2. Method *C*

Key: 1, Δ^4-Cholesten-3-one; 2, progesterone; 3, 17α-hydroxyprogesterone; 4, Reichstein's compound *S*; 5, hydrocortisone; *m*, mixture. Detection: sodium hydroxide fluorescence in ultraviolet (ref. 4)

partially acetylated paper and therefore irreproducible results are obtained. Recently, Zijp[2] described the identification and quantitative determination of rubber-antioxidants on fully acetylated paper, which is much more homogeneous.

We have obtained good separations of various groups of steroids on fully acetylated Whatman 1 paper, prepared by Zijp's method[3]. At first a one-phase mixture of benzene, methanol and water (1 : 10 : 3) was used as the mobile phase. Accommodation is not required in this case. The method is simple and quick, and reproducible R_F values are obtained, but some 'tailing' is usually observed (method *A*).

To prevent this, a two-phase mixture of benzene, methanol and water (4 : 4 : 1) was used, the lower layer (mainly benzene) being used for accommodation and the upper layer (mainly methanol) as the mobile phase (method *B*). A wide range of steroids from relatively weakly polar to strongly polar may be chromatographed in this way (Fig. 1).

It is also possible to use the upper (most polar) layer for accommodation and the lower layer as the mobile phase, so as to obtain 'conventional' chromatograms, in which the weakly polar steroids have larger R_F values than the stronger polar ones (method *C*). This method is especially convenient for the separation of strongly polar steroids such as the corticosteroids, but steroids less polar than progesterone move with the front (compare Figs. 1 and 2).

The R_F values (Table 1) seldom diverge by more than 0·02 from the average. The method has been applied to male sex hormones, progesterone, corticosteroids and their acetates, bile acids, cholesterol and oxidation products of cholesterol. The ascending technique was used in all cases.

Table 1. R_F VALUES OF STEROIDS AFTER CHROMATOGRAPHY ON FULLY ACETYLATED PAPER

Steroid	Method *A*	Method *B*	Method *C*
Testosterone acetate		0·27	
Δ^4-Androstene-3,17-dione		0·41	
Testosterone		0·57	
Progesterone		0·35	0·92
Deoxycorticosterone		0·45	0·80
17α-Hydroxyprogesterone		0·47	0·78
Reichstein's compound *S*		0·57	0·61
Cortisone		0·60	0·46
Hydrocortisone		0·68	0·39
Δ^5-Pregnen-3β-ol-20-one		0·40	
Deoxycorticosterone acetate		0·30	
Cortisone acetate		0·43	
Hydrocortisone acetate		0·51	
Deoxycholic acid	0·64		
Cholic Acid	0·74		
Cholesterol	0·33	0·10	
Δ^4-Cholesten-3-one	0·28	0·07	
7α-Hydroxycholesterol	0·59	0·38	
Δ^5-Norcholesten-3β-ol-25-one	0·42	0·31	

The same phase system may also be used for preparative purposes. Good separations have been obtained with thick paper (fully acetylated Whatman 3 *MM*) and with columns of paper disks or 'chromatopiles' (Schleicher and Schüll 2043 *a*, *vollazetyliert*). Experiments with columns of cellulose triacetate powder were somewhat less successful.

The quantitative determination after elution from the chromatogram and spectrophotometric evaluation at 242 mμ with respect to 240 mμ, showed that 80–120γ of cholestenone and progesterone may be determined with a relative error of less than 5 per cent.

A detailed report of this work will be published elsewhere.

A Modified Technique in Chromatography

The methods usually adopted for the chromatographic separation of inorganic radicals on filter paper or an adsorbent column lead to the formation of coloured zones with diffusion fronts which are distorted and irregular. We have now developed a method for obtaining sharp, straight and evenly coloured bands for each one of the radicals separated. Strips of Whatman filter paper (No. 1), are dipped in a hot agar sol (2–4 per cent) containing reagents which react with the radicals to be tested. The strips are then removed from the agar sol and the excess sol drained off, leaving a thin layer of the sol on the surface of the paper, which solidifies to a gel on cooling. The paper strip thus prepared is then immersed to a height of 5 mm. in an aqueous solution containing the radicals to be tested (the concentration of the solution being 0·1 *N* with respect to each ion). As the electrolytes diffuse into the agar-gel impregnated filter paper containing the appropriate reagents, sharp, straight zones of the characteristic coloured precipitates are produced. When the layer of the gel coating on the paper is thick, these coloured bands show a fine structure due to Liesegang ring formation. In a run of four hours, bands of sufficient width for accurate measurement with a travelling

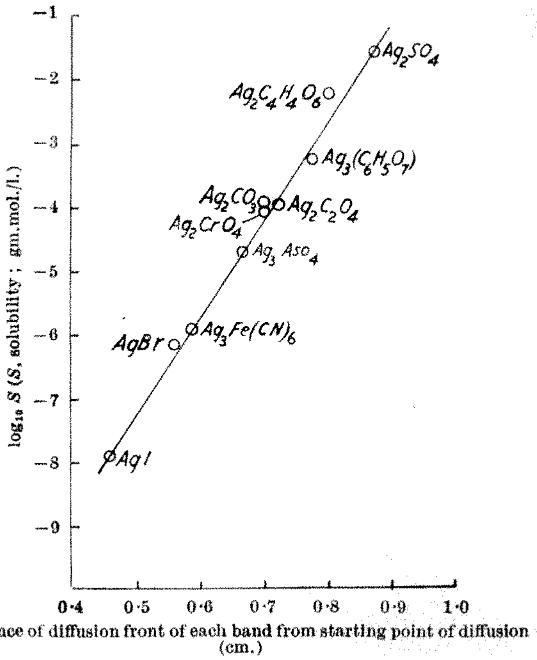

Fig. 1

microscope are produced in accordance with the solubility-product principle discussed previously[1].

Apart from the fact that a beautiful coloured band 'spectrum' is produced, the quantitative study of these bands has revealed a simple and striking relationship between d, the distance of the diffusion front of each band after a certain time from the starting point of diffusion, that is, the surface-level of the solution in which the gel-coated paper is dipped, and S, the solubility of the corresponding precipitate, namely :

$$d = a + b \log_{10} S$$

where a and b are constants. The validity of this relationship is brought out by the results represented graphically in Fig. 1.

Similar results have been obtained by allowing the electrolytes in the solution to diffuse for about six to eight hours into an agar gel layer containing the reagents spread on a glass slide. We have further observed that, when the gel layer is sufficiently thick (say 3–4 mm.), the individual coloured bands corresponding, for example, to lead, silver and copper chromates show a fine structure owing to their resolution into closely spaced lines corresponding to the Liesegang rings (see Fig. 2). The picture thus obtained is similar in appearance to an optical band spectrum viewed at high resolution.

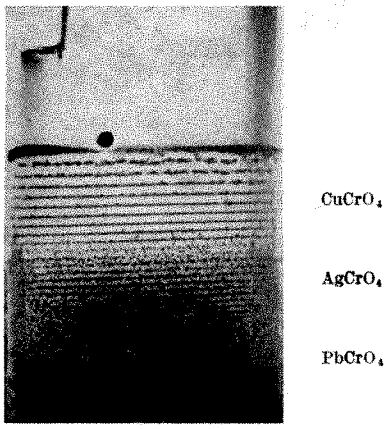

Fig. 2

We have thus worked out a new technique of chromatographic separation of inorganic ions, which also gives a new and simple method for the determination of the solubilities or solubility-products of various sparingly soluble substances. By this method we can separate the various hydrated ions in solution by their sizes ; for ions which on hydration have smaller sizes diffuse farther than those which, owing to their larger size, diffuse more slowly in accordance with the well-known diffusion equation.

In a previous communication[2] we have described a new method of determining the solubility products of sparingly soluble substances by means of the relation $\Delta v_\infty = c - b \log_{10} S$, where Δv_∞ is the limiting increase of volume observed on mixing dilute aqueous solutions of two electrolytes leading to the formation of the precipitate, and S is the solubility product ; c and b are constants. The change of volume, Δv_∞, indicates the water of ionic hydration released during the combination of ions, and is greatest for precipitates having the lowest solubility. Comparison of these results with those given earlier in this communication shows that the most insoluble inorganic precipitates are formed from hydrated ions having the largest size (including water of hydration), which consequently diffuse most slowly and produce the band in the 'chromatogram' nearest the surface of the electrolyte solution.

A Solvent for the Paper Chromatographic Separation of Glucose and Sorbitol

GLUCOSE and sorbitol can be separated by paper chromatography in 7 hr. by means of a solvent mixture which is composed of nine parts (by vol.) of ethyl methyl ketone, one part glacial acetic acid and one part of water saturated with boric acid.

This solvent was elaborated because, of the many solvent mixtures described for the paper chromatography of sugars, none appeared to be particularly effective for the separation of these two substances.

We use the descending technique in chromatography jars held at a constant temperature of 22° C. Whatman No. 54 paper gives rather better results than Whatman No. 1 ; separations with this latter paper are also somewhat slower. The solvent has given good results in this laboratory for some two years.

The rates of movement of sorbitol and some other sugars on No. 54 paper, as compared with glucose (R_G = 1·0), are shown in Table 1.

Table 1

Sugar	R_G	Sugar	R_G
Sorbitol	3·0	D-Xylose	2·9
Mannitol	2·5	D-Ribose	7·0

Chromatographic Separation of Œstriol, Œstrone and Œstradiol-17β

Non-ionic adsorption of aromatic substances on ion exchange resins discussed by D. E. Weiss[1] has been successfully utilized by me for the chromatographic separation of aromatic compounds, for example, alkylated phenols[2] and N-2 : 4-dinitrophenylamines[3], on the column of carboxylic acid type cation exchange resins, 'Amberlite *IRC*–50' and 'Duolite *CS*–101' (*H* form). The technique has now been extended to the chromatographic separation of œstrogens using partially esterified carboxylic acid type cation exchanger as adsorbent. About 30 ml. of 'Amberlite *IRC*–50' (*H* form: 200–300 mesh, screened wet in sodium ion form[4]) was boiled with 400 ml. of the mixture of ethanol and *N* hydrochloric acid (2 : 1 by vol.) for 40 hr. This partially esterified resin was washed with the mixture of ethanol and water (3 : 2 by vol.) and suspended in two volumes of the same mixture. The suspension was poured into a chromatographic tube and allowed to settle under gravity. A column 0·8 cm. in diameter and 62 cm. in height was used. Œstrogens were dissolved in the same solvent as that used for the packing of the column. 1 ml. of the solution was placed on the column and allowed to drain under gravity. Elution was performed with the same solvent and the effluent was collected in fractions of 40 drops. The ultra-violet absorption was measured at 280 mμ using a Beckman *DU* quartz spectrophotometer and plotted against fraction number (Fig. 1). The elution sequence was similar to that of reversed phase partition chromatography[5], the most polar component being eluted first. Recovery from the column was satisfactory and the elution pattern was reproducible. Since the condition of the column is unchanged after chromatography, the column can be used many times.

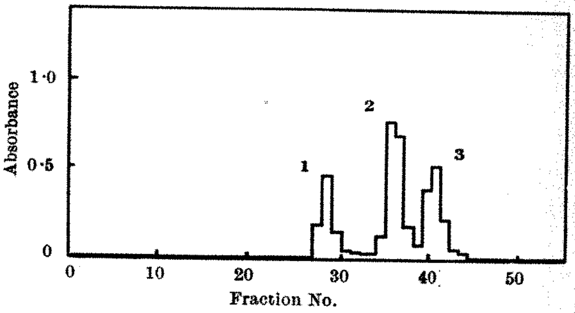

Fig. 1. Elution curve of œstrogens. 1, Œstriol; 2, œstradiol-17β; 3, œstrone. Flow-rate, 2 drops per min.; room temperature, 20° C.

Table 1. Recovery of Œstrogens from the Chromatographic Column

Œstrogens	Added (μgm.)	Recovered (μgm.)	Recovery (Per cent)
Œstriol	414	413	100
Œstradiol-17β	855	840	98
Œstrone	606	553	92

The application of this method for the quantitative analysis of urinary œstrogens is in progress and will be reported elsewhere.

I wish to thank Mr. K. Matsumoto for the generous gift of œstriol.

Determination of Epinephrine and Related Compounds on Paper Chromatograms

The most sensitive chemical method for determining epinephrine in solution is the reaction with ethylenediamine. The reaction yields a number of products, several of which are fluorescent. These substances can be used for quantitative measurement. Nor-epinephrine produces a fluorescence of different colour so that mixtures of the two compounds can be determined by the selection of appropriate filters in measuring the fluorescent light[1].

The number of products formed in this reaction was determined by chromatographing the products produced by the interaction of the diamine and various catechols. This was done on paper by using as solvent 5 per cent ammonium hydroxide and *n*-propanol (9 : 1). There are three to five fluorescent pigments (depending on the conditions of the reaction) and several coloured but not fluorescent ones. We have observed that epinephrine yields some products different from those given by nor-epinephrine, but under these conditions of chromatography the products from catechol, nor-epinephrine, hydroxytyramine and epinine migrate similarly. Also, adrenochrome produces the same products as adrenaline, supporting the contention[1] that the catechol–ethylenediamine reaction involves oxidation.

The addition of ferricyanide or iodine to the ethylenediamine does not change the qualitative nature of the fluorescent pigments, but does increase the amounts formed. Presumably by rapid oxidation of the catechol, one can prevent other side reactions which decrease the yield of fluorescent compounds. This was the reasoning used in making this reagent.

Potassium ferricyanide (0·1 per cent in 5 per cent aqueous ethylenediamine) or iodine (0·01 *N* in 5 per cent aqueous ethylenediamine) are most useful as oxidizing agents. The alkaline iodine solution is stable (room temperature) for only a few days, whereas the ferricyanide solution is considerably more stable (weeks). After spraying with either of these solutions, the chromatograms are placed in an oven at 50° C. for 5 min. We have used the light produced by a 'Sylvania Blacklite Blue' fluorescent lamp for examining the chromatograms. By this method, one can readily detect 0·05 μgm. of a catecholamine.

For the quantitative evaluation of the fluorescence considerably more elaborate methods have been evolved. Instead of spraying the chromatograms, the dipping technique has been used. The strip is dipped first into a 1 per cent solution of iodine in carbon tetrachloride, blotted, and before it is completely dried, dipped into a 1 per cent solution of ethylenediamine in *iso*propyl alcohol, and again blotted. The strip is then hung to dry at room temperature. The fluorescence of epinephrine appears within 30 min. whereas that due to nor-epinephrine and other catecholamines is much slower. The maximal difference between background and epinephrine fluorescence occurs in about 24 hr. At that time, the strips were scanned by means of a mechanical device which pulls the strip past the beam of a Beckman *DU* photometer equipped with a photomultiplier tube. The output of the photocell is recorded on a strip chart recorder. The 417-mμ light produces the maximal fluorescence. The exciting light is removed from the beam by a Corning colour filter 4015. The areas under the peaks are related to amounts of catecholamines by the use of a standard curve[2].

For example, 1 μgm. quantities of epinephrine were placed on four one-inch strips of Whatman 1 paper and chromatographed using *t*-butanol/formic acid/water (40 : 1 : 10) as the solvent. After 40 hr. (strips were cut so that the solvent dripped from the end) the strips were dried and treated as described above. Under these conditions, areas of 132, 130, 126 and 138 cm.^{2} were measured on the strip chart record of the fluorescence on these chromatograms. (It should be noted that the absolute areas have no significance as they are determined by the sensitivity of the photocell, the slit width, the brightness of the exciting beam, etc., as well as the amount of material on the chromatogram. Thus, it is necessary to compare the areas from the scans on unknown chromatograms with those on known amounts, using the identical conditions of scanning.) Using the most sensitive techniques (brightest exciting light, most sensitive position of the photocell) one can estimate 0·03 μgm.; for example, four chromatograms, prepared in the above way with 0·3 μgm., gave areas of 33, 41, 31 and 27 cm.^{2}.

Coding Problem in Proteins

In a previous publication[1] a hypothesis was proposed to the effect that if a nucleic acid serves as a template for the linear array of amino-acids in a protein, it prescribes only the positions to be occupied by the aromatic amino-acids in that protein. It was postulated that the planar rings of the aromatic amino-acids would be differentially bound in cavities formed by two adjacent bases in such a way that the aromatic amino-acids with only six-membered rings (group 1) would occupy the space between two pyrimidines and those with five-membered rings (group 2) would occupy that between two purines. This hypothesis imposes certain restrictions on the arrangement of these amino-acids in proteins. It requires that, sandwiched between a pair of aromatic amino-acids belonging to the same group, there will be either none or an even number of non-aromatic amino-acids, and that an odd number will separate aromatic amino-acids of different groups.

Much progress has been made in recent years in the elucidation of amino-acid sequences in proteins, affording further test for the restrictions imposed by the hypothesis. Phenylalanine does not conform to this scheme, and its position must therefore be specified in some other manner. However, with regard to the other aromatic amino-acids, tyrosine (group 1) and histidine and tryptophan (group 2), the spacing between the aromatic pairs is of the order required by the hypothesis in each of the twelve cases reported where such a test is possible. These sequences are listed in Table 1. If any arrangement of aromatic amino-acids were permissible, the probability of obtaining this result attributable to chance alone would be very small.

Silk fibroin (ref. 11)
  -TYR-pro-ser-TYR-

The non-randomness in the arrangement of the aromatic amino-acids offers support for the proposed coding system, although the lack of conformation of phenylalanine is a serious obstacle that must be overcome. It should be mentioned that phenylalanine stood apart from the other aromatic amino-acids even in the three protein sequences examined in the earlier paper. The observed restrictions suggest that the conclusion of Brenner[12], that "all amino sequences are likely to be found and that it will not be possible to effect a 'decoding' by discovering restrictions in sequences", may not be valid.

Specificity of Crystalline Saccharogenic Amylase of Moulds

AMONG the saccharogenic amylases of moulds hitherto reported, γ-amylase of *Aspergillus awamori* Kitahara[1], gluc-amylase of *Rhizopus delemar*[2] and taka amylase *B* of *Aspergillus oryzae*[3] seem to be the most characteristic in their mode of hydrolysing starch. All these amylases, belonging to the group of amylo-(1.4)-glucosidases suggested by Schubert[4], have already been purified to a certain degree and reported as being able to split glucose directly from starch. γ-Amylase, however, has been known to leave a limit dextrin when it acts on amylopectin and to show no maltase activity. Gluc-amylase has been reported to hydrolyse soluble starch in such way that with the iodine colour test of the reaction mixture the blue colour still remains even after the starch, calculated as glucose, is more than 90 per cent hydrolysed. The enzyme has also been found to hydrolyse amylopectin almost completely to glucose and to exhibit maltase activity. Taka amylase *B*, on the other hand, has been reported as being similar to γ-amylase in the hydrolysis of amylopectin, but exhibiting maltase activity.

Recently, we have obtained in a crystalline state the two saccharogenic amylases of *R. delemar*[5] and of *A. niger*, of which the specificity of the latter is very similar to that of taka amylase *B* (Figs. 1 and 2), starting from the enzyme preparation that was isolated as almost the pure enzyme solution by the Svensson and Brattsten paper electrophoresis apparatus with the flow system[6]. The two saccharogenic amylases were completely free from α-amylase and both showed a single boundary in an electrophoresis experiment. The two crystalline amylases formed glucose directly from starch and hydrolysed maltose. They exhibited neither transglucosylation activity on a substrate of maltose nor were they able to hydrolyse *iso*maltose and dextran. However, as shown in Fig. 3, these amylases were found to hydrolyse panose(4-*iso*-maltopyranosyl-D-glucose), in which glucose and maltose were formed, the latter being hydrolysed successively to glucose and no *iso*maltose was produced. As for the panose-hydrolysing activity, however, the saccharogenic amylase of *R. delemar* was much stronger than that of *A. niger*, at an equal level of their starch-hydrolysing activity. Another difference between the two saccharogenic amylases was found in the limit of hydrolysis of soluble starch and amylopectin. The saccharogenic amylase from *R. delemar* easily hydrolysed these substrates, converting them almost completely to glucose; on the other hand, that from *A. niger* converted about 75 per cent of soluble starch and about 70 per cent of amylopectin, and an extremely large amount of the enzyme was required to increase these degrees of hydrolysis (Fig. 4). The crystalline amylase from *R. delemar* hydrolysed several kinds of substrates with the initial velocities in the following decreasing order: glycogen, amylopectin, soluble starch, α-dextrin, amylose, panose and maltose.

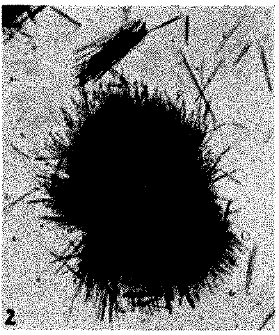

Fig. 2. Crystalline saccharogenic amylase of *A. niger*

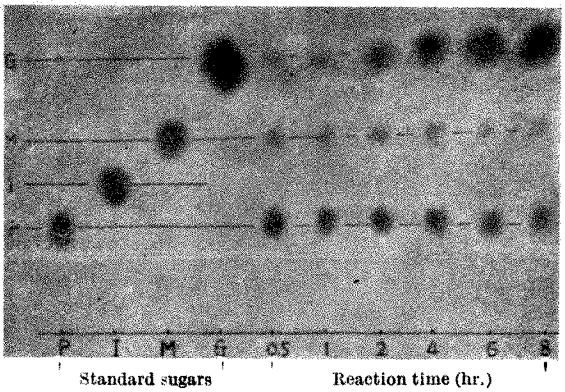

Fig. 3. Multiple ascending paper chromatogram of panose digests by crystalline saccharogenic amylase of *R. delemar*. Solvent, pyridine/butanol/water (2 : 3 : 1·5); standard sugars: *G*, glucose; *M*, maltose; *I*, *iso*maltose; *P*, panose

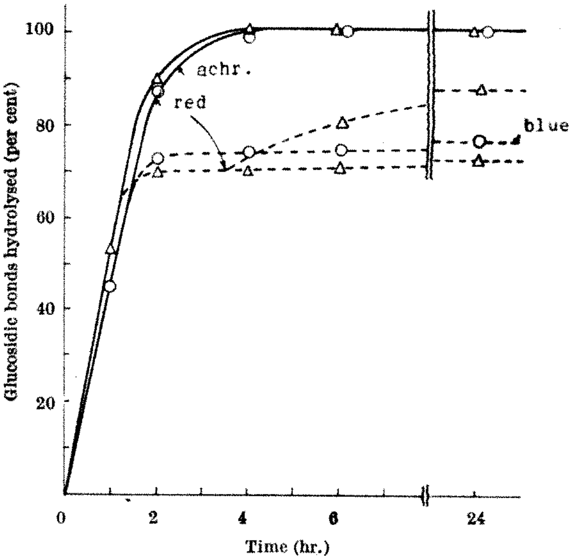

Fig. 4. Hydrolysis of soluble starch (○) and amylopectin (△) by saccharogenic amylases of *R. delemar* (solid line) and by *A. niger* (broken line). *Red* and *achr.* indicate the colour change of the reaction mixture from blue to red and to colourless respectively, by the iodine test. The long arrow indicates the addition of one thousand times the original amount of enzyme

Earlier, Underkofler[7] published an account of limit dextrinase, which appears to be consistent with that of taka amylase *B* of *A. oryzae*. Also, Yamasaki[8] and Ueda[9] have reported that the saccharogenic amylase system of *A. awamori* Kawachii completely hydrolyses several kinds of starches, and that the enzyme system consists both of saccharogenic amylases of *R. delemar* type and taka amylase *B* type. The limit dextrinase action or the ability to hydrolyse starch completely of such saccharogenic amylase as that of *R. delemar* might be explained by its powerful activity in hydrolysing panose, since amylopectin and its fission products by α-amylase appear to be hydrolysed, at first to α-1.6-linked oligosaccharides of panose type on their non-reducing ends by the amylo-(1.4)-glucosidase action of the amylase, and the oligosaccharides formed therein to be further hydrolysed by this panose-hydrolysing action.

We are indebted to Dr. K. Shibasaki, of Tohoku University, for supplying the *iso*maltose and panose used in this work.

Degradation of Steroidal Sapogenins to 16-Dehydropregnan-20-ones

THE need for improving the reactions whereby steroidal sapogenins, now in abundant supply, are transformed into pregnane derivatives has recently been re-emphasized[1]. Earlier publications have dealt definitively with the entire sequence, so that the original Marker procedure has now been improved at each stage[2].

A modification offered here converts the sapogenin to its corresponding 16-dehydropregnan-20-one acetate, generally in 50–75 per cent yield of isolable product, without the necessity of separating any intermediates or changing the character of the reaction medium along the way. For example, 88 gm. of tigogenin was heated 25 min. with 450 cm.^{3} of acetic anhydride; 30 gm. of pyridine hydrochloride was added and heating continued for 3 hr. The mixture was cooled to 15° C., diluted with 50 cm.^{3} of acetic acid and 79 cm.^{3} of water and stirred while adding 54 gm. of chromic anhydride in 500 cm.^{3} of 90 per cent acetic acid. The temperature was maintained at 16–20° C. After standing at 25° C. for 3 hr. the solution was treated first with 31·5 gm. of 36 per cent formaldehyde and then with 80 gm. of sodium acetate. The stirred suspension was heated on the steam-bath for 1 hr., cooled in ice and diluted gradually with 3,000 cm.^{3} of cold water. A white, granular precipitate was collected, washed and dried; it melted at 120–150° C., weighed 82·1 gm. and by ultra-violet absorption contained 73 per cent of the 16-dehydropregnane. It was adsorbed from benzene on to fifteen parts of silica gel and the product eluted directly with 5 per cent ethyl acetate in benzene to give 51·6 gm. or 68 per cent of 3β-acetoxy-16-dehydro-5α-pregnan-20-one (melting point 162–167° C., $\epsilon_{\text{max.}\,(240\,\text{m}\mu)}$ 9,300 in methanol). When recrystallized twice from methanol, material of analytical quality (melting point 168·0–169·2° C., $[\alpha]_D$ 37·5° (chloroform)), $\epsilon_{\text{max.}\,(240\,\text{m}\mu)}$ 9,460 (see ref. 3), was obtained in an overall yield of 45 per cent (value extrapolated from smaller sample).

In other instances the initial heating with acetic anhydride has been omitted; also with smaller quantities the usual ether extraction of the final mixture has been used. Thus, 20 gm. of a mixture of ruscogenin and its C_{25} epimer gave 20·6 gm. of extractable material of which 11·2 gm. (59 per cent yield) of the desired 16-dehydropregnane, a glass[4] ($\epsilon_{\text{max.}\,(240\,\text{m}\mu)}$ 9,460) was obtained by direct elution with 5 per cent ethyl acetate. Hecogenin treated in the same manner yielded 59 per cent of crystalline 3β-acetoxy-16-dehydro-5α-pregnane-12,20-dione, (melting point 179–185° C.) from the eluates.

This method offers the advantages of speed and simplicity. It has been applied as a matter of routine to sapogenins and derivatives with uniform success.

A Rapid and Specific Method for the Isolation of Pneumococcal Polysaccharide

THE report by Gessler *et al.*[1] on the use of a completely substituted ethane (trichlorotrifluoro ethane, 'Genetron 113'; obtained from the Division of Allied Dye and Chemical Corp., General Chemicals, Inc., New York) as a 'deproteinizing' agent in the purification of influenza virus, suggested to us that this solvent might have many uses. In particular, we were concerned with 'deproteinizing' bacterial cells with the consequent release of polysaccharides. In view of the observation that this solvent is not miscible with water and that pneumococcal polysaccharide is soluble in water, the following experiment was performed.

D. pneumoniae, type I, smooth-phase cells were grown on beef heart infusion agar, harvested in 18 hr., washed several times and the concentration optically adjusted to 10^9 cells per millilitre of buffered saline, *p*H 7·2.

One part of cells to three parts of solvent were agitated for ten minutes in the high-speed homogenizer at maximum speed, removed and then centrifuged at 1,500 r.p.m. for 10 min. Three layers resulted: (1) an upper aqueous layer, (2) a middle gel-like layer, and (3) a bottom layer of solvent. The upper water layer was removed and treated as above for three more successive solvent extractions. During such treatment further gel-like material was removed.

The final water layer was tested for immunological activity by use of the interfacial-precipitin test using antiserum prepared against whole smooth cells. A positive reaction resulted immediately upon contact.

After concentration by evaporation in a dialysis casing with a fan, it was determined that the material extracted was strongly Molisch-positive, ninhydrin-negative and upon paper electrophoresis showed no indications of containing protein. Moreover, ultraviolet absorption tests did not indicate any absorption at 2600 A., thus ruling out the possibility that water-soluble nucleoproteins might be present.

That the extract was not the *C* somatic polysaccharide was ruled out in two ways. With alcohol precipitation we recovered all the material in the water layer by the addition of 1·5 volumes of 95 per cent ethanol, and secondly, we did not obtain a positive precipitin reaction when rabbit anti-*C* anti-serum was employed.

Few data are available on the chemical and physical properties of this particular polysaccharide, and we examined only those properties which had been reported. The $[\alpha]_D$ of our material was +260° as compared to a reported[2] range of +253 to +278°. Acid hydrolysis followed by chromatography indicated galacturonic acid and an unidentified amino-containing material. Nitrogen values of 4·82 per cent were also obtained.

In view of the correlative findings obtained it is felt that a rapid and apparently specific method for the isolation of the pneumococcal polysaccharide has been obtained. With the present interest in bacterial polysaccharides (lipo-polysaccharide endotoxin studies) such a procedure might very well serve to obtain large amounts of microbial polysaccharides more rapidly and possibly more specifically than existing methods. One of us (A. S. M.) has also utilized this method for tissue polysaccharides and finds it just as specific. Experiments under way are designed to test the applicability of this method to a wide variety of microbial polysaccharides.

A New Synthesis of Histidyl Peptides

Although many peptide groups containing L-histidine have been found in the biologically active substances, for example, insulin, ribonuclease, adrenocorticotropic hormones, etc., no satisfactory method for the synthesis of the histidyl peptide has been so far reported. As a starting material, N(α)-carbobenzoxy-L-histidine is not suitable except for the azide route[1], because it is scarcely soluble in the usual organic solvents. We have devised a simple synthetic method for the preparation of the histidyl peptide from dicarbobenzoxy histidine.

N(Im),N(α)-dicarbobenzoxy-L-histidine was prepared in 81 per cent yield from L-histidine monohydrochloride monohydrate and carbobenzoxychloride by the usual Schotten–Baumann method. In this procedure sodium carbonate was used as the condensation reagent instead of sodium hydroxide. The dicarbobenzoxyhistidine produced, which was readily soluble in organic solvents, was available for the synthesis of the histidyl peptide.

5 gm. of L-histidine monohydrochloride monohydrate was dissolved in 48 ml. of 1 *N* sodium hydroxide solution and, after addition of 5·3 gm. of sodium carbonate, 8·1 gm. of carbobenzoxychloride was added gradually to the solution with vigorous stirring at 0° C. for 1–1½ hr. As the reaction proceeded, the product was precipitated. The reaction mixture was allowed to stand at room temperature for ½–1 hr. with stirring. Then it was brought to *p*H 3·0 with 6 *N* hydrochloric acid. The gelatinous mass produced was separated from the supernatant by decantation and was triturated with 15–30 ml. of 99 per cent ethanol. The white crystals were collected and washed with 99 per cent ethanol. The yield was about 8·6 gm. (81 per cent). Recrystallization from acetone–water gave white needles of N(Im),N(α)-dicarbobenzoxy-L-histidine (melting point 103–105° C. (dec.); $[\alpha]_D^{14} = +34{\cdot}01$ (*c*, 28·99 mgm./ml. ethyl acetate); calc. for $C_{22}H_{21}O_6N_3.H_2O$, C, 59·86, H, 5·25, N, 9·52 per cent; found, C, 59·64, H, 5·11, N, 9·46 per cent; water of crystallization: calc., 4·08 per cent, found, 4·19 per cent).

The product is easily soluble in ethyl acetate, acetone, benzene, dioxane, tetrahydrofurane and chloroform, moderately soluble in ether, warm methyl alcohol and warm ethyl alcohol, and insoluble in water and petroleum ether. It is unstable in both alkaline and hot acidic solutions.

The carbobenzoxy groups were removed with hydrogen-bromide glacial acetic acid or with concentrated hydrochloric acid at 37° C., and the resultant product was found to be identical with the authentic L-histidine.

Some dicarbobenzoxypeptide derivatives were synthesized by Sheehan's method[2]. Derivatives of L-histidyl-O-benzyl-L-serine methyl ester, L-histidyl-L-leucine methyl ester, L-histidyl-L-threonine methyl ester, L-histidyl-L-glutamic acid diethyl ester and L-histidyl-L-methionine methyl ester were prepared from dicarbobenzoxy-L-histidine monohydrate and the corresponding amino-acid esters using dioxane or chloroform as a solvent in 81, 68, 79, 70 and 85 per cent yield, respectively. Melting points, specific rotatory power and analytical data of some dicarbobenzoxyhistidyl peptide esters are shown in Table 1.

It was shown in the preliminary experiment that dicarbobenzoxy-L-histidyl-L-leucine methyl ester underwent both saponification of ester and removal of the carbobenzoxy groups simultaneously by the treatment with concentrated hydrochloric acid at 37° C. for 50 min. and was converted to L-histidyl-L-

Electrophoretic Behaviour of *i*-Urobilin and Stercobilin

As the urobilinoid pigments *i*-urobilin and stercobilin are known to contain both basic and acidic groups, we have investigated their electrophoretic behaviour—yet unstudied—at various *p*H values. Paper electrophoresis was performed at 120 V., in acetate buffer (a mixture of *M*/5 acetic acid–sodium acetate buffer and 0·9 per cent sodium chloride solution) in the *p*H range less than 6·0, and barbital buffer (Michaelis sodium barbital–sodium acetate–hydrochloric acid buffer) at *p*H greater than 6·0; the positions of the coloured spots were observed directly during the procedure, but even minute quantities of urobilinoid pigments could be seen at the end of the run after spraying the papers with Schlesinger reagent (saturated zinc acetate solution in ethanol), and observing the green fluorescence in ultra-violet light. With the exception of the sharply defined *p*H value of 4·41 at which both urobilinoid pigments became immobile in the electric field, they moved towards the cathode at *p*H less than 4·41 and toward the anode at *p*H greater than this value, the direction of movement, which was the same for both pigments, being dependent only on the *p*H. However, the rate of movement of these materials differed at various *p*H levels: thus in buffers around *p*H 5·0 and at *p*H less than 4·41 stercobilin migrated faster toward the anode or cathode, respectively, whereas at higher *p*H values (8·6) urobilin was found to move faster than stercobilin in the anode direction.

As these substances are known to be ionized even at their isoelectric point[1], the basic and acid groups were found to be in equilibrium in the electric field around *p*H 4·41, but below this isoelectric point the direction of migration is determined by the ionized basic groups, and above this *p*H value by the ionized acid groups.

Fig. 1. Diagrams of electrophoresis paper strips. *St*, stercobilin; *U*, *i*-urobilin; arrow indicates migration in anodic or cathodic direction. Environment: (*a*) barbital buffer solution, *p*H 8·6; 7-hr. run; (*b*) acetate buffer, *p*H 5·5; 8-hr. run; (*c*) acetate buffer, *p*H 3·8; 4-hr. run; (*d*) electrophoretic behaviour of zinc complexes of urobilinoid pigments in barbital buffer, *p*H 8·6; 1-hr. run. Part of urobilin left the starting line

As the *pK* of stercobilin is known from spectrophotometric determinations[2] to be 8·0, at *p*H 8·0 only half the molecules of this substance are dissociated, whereas at the same *p*H *i*-urobilin characterized by *pK* 7·0 is far more completely dissociated, hence the greater mobility of the latter at *p*H 8·0, above its *pK*. This more acid character of *i*-urobilin and more basic property of stercobilin may be explained on the basis of the lactam structure of urobilinoid pigments proposed by Birch[3] and verified by Gray and Nicholson[4]. The NH-groups of the end rings attached to a conjugated system of double bonds in urobilin impart a greater acidity than the NH-groups in stercobilin behaving as ordinary amides. The nitrogen atom of an ordinary amide may more readily be protonated than the nitrogen atom of the end rings of urobilin; hence the faster migration of urobilin at high *p*H and of stercobilin at low *p*H.

However, the electrophoretic separation of stercobilin and *i*-urobilin is not yet sufficient for the practical isolation of either material from the other, but they may be isolated, with the aid of their electrophoretic behaviour, from mixtures containing the bile pigments.

The zinc complexes of the urobilinoid pigments were immobile during the electrophoretic procedure and could be detected at the 'start' position without spraying. However, their stability was limited, part of the pigments successively leaving the starting point and behaving as urobilinoids containing no zinc. The stability of zinc stercobilin proved more resistant to the action of the electric field than zinc *i*-urobilin.

I wish to thank Prof. C. J. Watson for sending samples of pure materials, as well as Dr. J. Toth for his valuable advice.

A Possible Basis for the Anti-inflammatory Activity of Salicylates and other Non-Hormonal Anti-Rheumatic Drugs

RECENT studies have shown that sodium salicylate and acetyl-salicylic acid increase oxygen consumption in rats, rabbits and man[1-3]. Sproull has shown that both sodium salicylate and 2 : 4-dinitrophenol stimulate metabolism in mouse-liver slices[4], but has recently found a difference between the slopes of the concentration–response curves for the two compounds[5]. Reid has also directed attention to these similarities, and has shown that both compounds inhibit the growth of wheat coleoptiles[6]. Cochran[3] suggested that the stimulation of respiration by salicylate may be of fundamental importance in the therapeutic action of the drug.

2 : 4-Dinitrophenol is known to uncouple oxidative phosphorylation in mitochondrial preparations[7], and Brody[8] and Penniall *et al.*[9] demonstrated that sodium salicylate and acetylsalicylic acid also uncouple in very low concentrations. Smith and Jeffrey[10] pointed out that most of the previously observed effects of

salicylates on carbohydrate metabolism could be explained satisfactorily in terms of the uncoupling of oxidative phosphorylation.

The possibility occurred to us that the anti-inflammatory activity of non-hormonal anti-rheumatic drugs might be related to their capacity to uncouple oxidative phosphorylation. These ideas have recently been strengthened by the preliminary findings of M. J. H. Smith (private communication) that phenylbutazone in a concentration of 7·5 mgm./100 ml. completely inhibits the uptake of inorganic phosphate accompanying the oxidation of β-hydroxybutyrate by mitochondria prepared from rat-liver. At a concentration of 4 mgm./100 ml., phenylbutazone uncoupled oxidative phosphorylation to the extent of about 80 per cent.

The anti-inflammatory effects of a number of compounds have therefore been examined and compared with their reported ability to increase oxygen-consumption *in vivo*, or to uncouple oxidative phosphorylation *in vitro*.

For the measurement of anti-inflammatory activity we used a modification of the ultra-violet erythema test first described by Wilhelmi[11]. In this, a small area of the depilated back of a guinea pig was exposed for 20 sec. to the ultra-violet radiation from a Hanovia 'Kromayer' lamp. Animals received test-substances or saline by mouth 30 min. before irradiation, and 120 min. later the degree of erythema was estimated visually, and given a score 0–4. By using graded doses it was possible to obtain an approximate *ED*50 for those compounds which inhibited the erythema. Sodium salicylate, aspirin and phenylbutazone were all active in doses which were approximately related to their clinical anti-rheumatic doses.

The results obtained in this test, together with such data as are available on the effects of the compounds on oxidative phosphorylation *in vitro* and on oxygen consumption *in vivo*, are given in Table 1. The results for the effects of the compounds on oxygen consumption were obtained by Meade in rats[1], except for the information on 2 : 4-dinitrophenol, which was obtained by Reid[2] in rabbits. The data relating to the uncoupling of oxidative phosphorylation were obtained from Brody[8], except that for phenylbutazone[11] and 2 : 4-dinitrophenol[5].

Table 1. A COMPARISON OF THE EFFECTS OF A NUMBER OF COMPOUNDS ON THE INHIBITION OF ULTRA-VIOLET ERYTHEMA IN GUINEA PIGS, WITH OXYGEN CONSUMPTION IN RATS OR RABBITS, AND WITH THE UNCOUPLING OF OXIDATIVE PHOSPHORYLATION *in vitro*

+, Active; —, inactive; blank, not known.

It will be seen that there is a general parallelism between erythema inhibition, the increase in oxygen-consumption and uncoupling activity. The fact that the three most active non-hormonal anti-inflammatory compounds, experimentally and clinically, have been shown to uncouple, points to the possibility of a connexion between therapeutic activity and uncoupling.

Exact parallelism of the various properties is not to be expected since considerations of tissue distribution are likely to play a greater part in the *in vivo* tests than in the *in vitro* methods. Nevertheless, there are several inconsistencies. 2 : 3-Dihydroxybenzoic acid is inactive in our test and does not increase oxygen-consumption, though its capacity to uncouple was demonstrated by Brody who, however, found it to be less active than sodium salicylate. On the other hand, phenazone, which was slightly active in the erythema test, did not uncouple. The outstanding discrepancy, however, is the failure of 2 : 4-dinitrophenol to affect the erythema test. The explanation of this may lie in a difference between 2 : 4-dinitrophenol and salicylates in the site of uncoupling.

It is interesting, in view of the stress now being placed on the similarity of action of salicylates and 2 : 4-dinitrophenol, to note this different behaviour in a test which apparently bears some relationship to therapeutic efficiency.

Direct Registration of an Instantaneous X-Ray Effect in Rats and Man

In order to study chemoprotection against radiation damage we tried to find radiobiological reactions as near as possible to the primary radiochemical process. In this we were guided by the assumptions that we must look for this in macromolecular systems and that we might find most radiosensitivity outside the domain of natural chemoprotection against oxidative or reductive radicals, that is, the respiring cytoplasm.

As radiobiological investigation of nuclear macromolecules does not easily lead to an instantaneously observable reaction, we restricted our research to a well-known system of extracellular macromolecules: the mucopolysaccharide matrix of the dermis connective tissue fibrils. The simplest way to study X-ray influence on the properties of the native matrix mucopolysaccharides is by collecting synovia and measuring its viscosity[1].

It was found that a moderate X-ray dose (500 r.) will at once decrease synovial viscosity by about

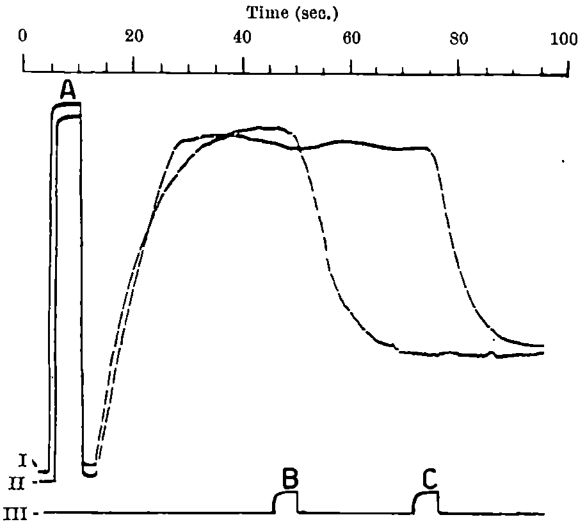

Fig. 1. Effect of X-irradiation on the intradermal injection pressure in the rat. I, II, pressure recordings of double injection apparatus. Injection with 0·9 per cent sodium chloride; III, irradiation signal; *A*, calibration (~ 100 mm. mercury); *B*, irradiation of I; *C*, irradiation of II. Dose-rate, 100 r./sec., 20 kV.

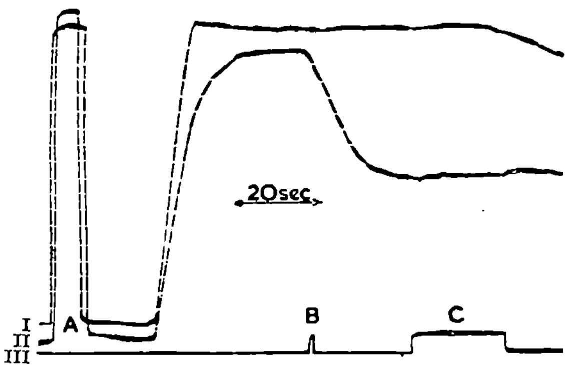

Fig. 2. Chemical protection by cystamine against the X-ray-induced pressure drop. I, II, pressure recordings of double injection apparatus. I, injection of 0·9 per cent sodium chloride with 0·01 per cent cystamine; II, injection of 0·9 per cent sodium chloride; *A*, calibration (~ 100 mm. mercury); *B*, irradiation of II; *C*, irradiation of I. Dose-rate, 100 r./sec., 20 kV.

20 per cent. It was also possible, by using an Epprecht Viscoprintmeter, to register a considerable drop in viscosity in 10 min. during irradiation with 200 r. per min. The radiation depolymerizing process is not complete, as addition of hyaluronidase to the irradiated product will cause a much greater depolymerization.

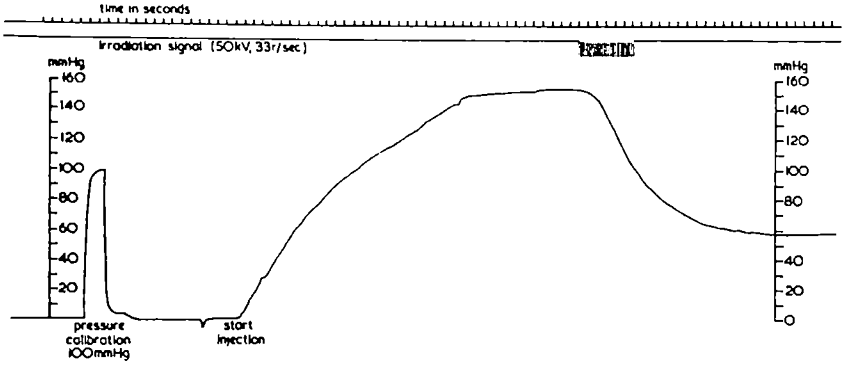

Fig. 3. Effect of X-irradiation on the intradermal injection pressure in the human forearm

We then applied similar or smaller X-ray doses to the mucopolysaccharide matrix in the rat's abdominal muscle fascia, the cock's comb and finally to rat and human dermis. We measured the effects by Day's permeability method[2] for the fascia, and registration of slow injection pressure for the others. The details will be described elsewhere[3].

Some results are given in Figs. 1 and 2. 1 ml. of saline was injected slowly, intradermally, at constant velocity, and the pressure set up by the matrix resistance to fluid motion was measured electronically. This pressure reached a constant level of about 100 mm. of mercury in 5–10 sec., and fell rapidly on irradiation at 100 r. per sec.

Fig. 1 is a photokymograph pressure record from a double injection apparatus, the needle tips being irradiated at *B* and *C*, in the nembutalized rat. Fig. 2 is a similar record, needle I injecting saline with 0·01 per cent cystamine and needle II serving as a control. Fig. 3 is a micrograph record of the slow injection of saline into the human volar forearm dermis. A distinct decrease of matrix resistance is seen with 200 r.

With a fine needle (No. 20) inserted well into the dermis connective tissue these phenomena are easily reproducible and well suited for the investigation of local chemoprotection. The results may be valuable for a more general chemoprotection.

Changes in the Topographical Distribution of Glycogen in the Brain during Animal Hypnosis

Animal hypnosis is a general biological reaction of an inhibitory type, which is analogous to several syndromes of human psychopathological behaviour[1]. Its phenomenology is widely known, but its mechanism and metabolic basis remain unsolved[2].

A study of some of the problems of the mechanism of animal hypnosis has shown that at the onset an important part is played by certain functional units of the brain stem[3,4]. It is therefore possible to assume that the characteristic electrical manifestations of the brain-stem function are also related, in the course of this reaction, with metabolic processes which differ from the metabolism of other parts of the brain. As an indicator of changes in metabolic processes of different parts of the brain glycogen was chosen, because it is known that different functional states of the brain and different symptoms of behaviour are accompanied by changes in its concentration[5,6].

Animal hypnosis was evoked by a 180° rotation of rats about the vertebral axis in an apparatus which

Table 1. CONCENTRATION OF GLYCOGEN IN THE COURSE OF ANIMAL HYPNOSIS

1·00			134·7 ± 9·8	6	130·9 ± 6·6	6			139·5 ± 9·6	6

Key as in Table 1.

makes possible a standard method of rotation. It is possible to attain in this way in the rat a state of sleep in a supine position which lasts for several minutes. The criterion of sleep evoked in this way is the absence of Magnus's righting reflexes which make the correct geotropic orientation of the animal possible. Animals were killed by decapitation into liquid air at various time intervals during hypnosis, as well as after arousal, and the concentration of glycogen was determined in the brain cortex, the diencephalon, mesencephalon, cerebellum and medulla oblongata by Kerr's method[7] except that the reduction compounds were determined after Nelson[8].

It can be seen from Table 1 that soon after the onset of animal hypnosis there is a significant increase in the concentration of glycogen in the diencephalon (after 0·05 min. $P < 0{\cdot}05$, after 0·10 min. and later $P < 0{\cdot}01$). Almost simultaneously glycogen begins to rise in the mesencephalon (after 0·10 min. $P < 0{\cdot}05$, after 1·00 min. and later $P < 0{\cdot}01$), while in the medulla oblongata significant changes appear later (after 1·20 min. $P < 0{\cdot}02$, after 1·30 min. $P < 0{\cdot}01$). There were no significant changes in the concentration of glycogen found in the cerebral cortex and in the cerebellum during the whole course of animal hypnosis.

As is shown in Table 2, there is a sudden decrease of glycogen in the medulla oblongata during arousal from animal hypnosis (the value after 0·01 min. is statistically not significant compared to the control). After 0·10 min. a decrease to values not significant when compared with the controls also occurs in the diencephalon. The same appears in the mesencephalon 0·20 min. after arousal. In general, the sequence in which the glycogen concentration returns to normal in topographically different parts of the brain after arousal is exactly opposite to the sequence of its increase during animal hypnosis.

The topographical distribution of changes in the glycogen concentration of the brain indicates that during animal hypnosis there are changes of the polysaccharide metabolism in the diencephalon, mesencephalon and the medulla oblongata, that is, in the brain stem structures, which according to electrophysiological findings also participate in this reaction. Similar changes take place in the course of natural sleep[4,9]. This finding, together with quite different changes in the topographical distribution of glycogen in the brain during pharmacological depression[10], indicates that animal hypnosis and natural sleep are probably similar forms of cerebral inhibition.

Occurrence of Ornithine in Sulphur-deficient Flax and the Possible Place of Ornithine and Citrulline in the Arginine Metabolism of Some Higher Plants

ALTHOUGH arginine has been recognized as a constituent of higher plants for many years, both as a structural unit in the protein and as the free amino-acid, two other components of the 'ornithine cycle' of animals, citrulline and ornithine, were not considered to be normal constituents of these plants. Wada, in 1930, isolated citrulline from *Citrullus vulgaris* Schrad.; but it was not again reported in higher plants until 1952, when Virtanen and Miettinen[1] detected it in *Alnus incana* L. and *Alnus glutinosa* L. Citrulline is now known to occur as a free amino-acid in plants of a number of families.

Evidence of ornithine in higher plants remains fragmentary. It has been detected chromatographically in *Hevea brasiliensis*, Müll.-Arg.[2], *Atropa belladonna* L.[3], *A. glutinosa*[1] and *Asplenium nidus* L.[4].

I have proved the presence of free ornithine in sulphur-deficient flax (*Linum usitatissimum*) plants where it is associated with citrulline and a large accumulation of arginine. The plants were grown and the amino-acid content examined as previously described[5]. Free ornithine was first detected in the plant extracts by the position of the ninhydrin-positive spot on two-dimensional chromatograms and by its reaction with vanillin[6]. Isolation of a larger quantity of ornithine was then attempted. A preliminary separation of the basic amino-acids in the plant extract was effected by using displacement chromatography[5] on 'Amberlite *IR* 120' and '*IR* 410'. This procedure also allowed a separation of arginine, which was a major constituent, from the other basic substances. One-dimensional paper chromatography was used to follow the progress of the isolation. The basic mixture at this stage contained citrulline, ornithine, traces of lysine and two unidentified ninhydrin-positive substances. Dinitrophenylation of these substances was effected by shaking an alkaline aqueous solution with a slight excess of 1,2,4-fluorodinitrobenzene for 2 hr. at 40° C. Excess fluorodinitrobenzene was extracted with ether and the solution acidified to *p*H 2. 2,4-Dinitrophenyl ornithine was separated from the mixture by extraction with 5 per cent butanol in benzene (v/v). The 2,4-dinitrophenyl ornithine was finally purified by repeated crystallization from methanol. Comparison of the X-ray powder photographs of this and the 2,4-dinitrophenyl derivative of pure ornithine confirmed chromatographic evidence that ornithine was a constituent of the plant material. (Thanks are due to the Mining and Metallurgy Department of the University of Queensland for taking these photographs.)

The presence of ornithine in association with citrulline and arginine in sulphur-starved flax and the roots of *A. glutinosa*[1] suggests that the classical ornithine cycle, which is known to operate in the mould, *Neurospora crassa*[7], may be a factor in the nitrogen metabolism of higher plants. However, with few exceptions, it has not been possible to demonstrate the presence of the enzyme arginase in higher plants, and it would appear that the production of urea from arginine is not an important metabolic process in such plants. Nevertheless the association of ornithine with citrulline and arginine in flax and *A. glutinosa* is of interest, particularly when it is coupled with the observations of Coleman and Hegarty[8], who have shown that DL-ornithine-2-^{14}C is readily metabolized by white clover and barley, citrulline and arginine being formed in appreciable quantity. They concluded from their experiments that enzymes effecting the conversion were operative in white clover and barley, though their presence was not confirmed by isolation.

It is suggested that in sulphur-starved flax the accumulation of ornithine and citrulline occurs as a result of a disruption in arginine metabolism. In a number of micro-organisms, some of which lack arginase, arginine is synthesized from ornithine via citrulline[9]. The reaction sequence ornithine, citrulline, arginine in these organisms is then not restricted to urea formation, but represents a general pathway for providing the arginine of cellular protein.

Influence of DDT and Lindane on Chordotonal Organs in the Cockroach

THERE has been much interest recently in stretch and strain receptors in Arthropods. Wiersma *et al.*[1] studied the responses of paired 'muscle receptor organs' in decapod Crustacea; these consist of

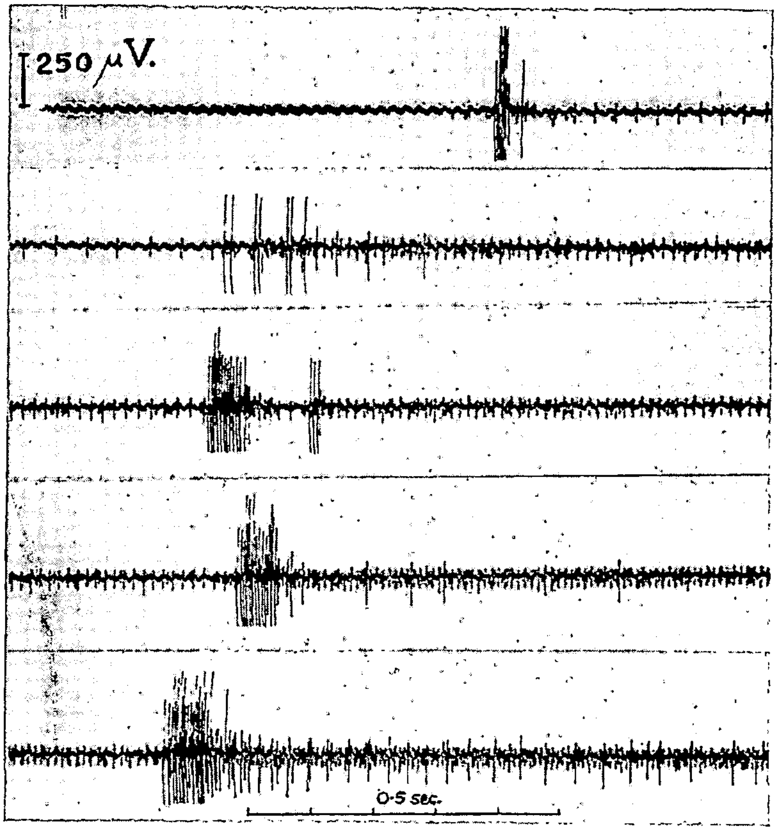

Fig. 1. Normal response of chordotonal organs in the coxa. Stepwise increase of mechanical tension produces an increasing frequency of small-amplitude impulses; the movement itself produces a burst of large spikes

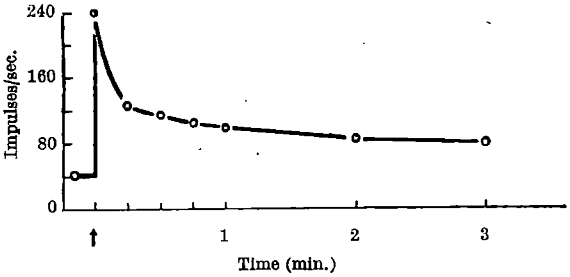

Fig. 2. Adaptation of a tonic receptor to constant tension. Tension applied at the arrow. Spontaneous activity 40 sec.$^{-1}$

muscle fibres with intercalated tendinous regions and are located dorsally in the abdomen and thorax. They found a slowly adapting unit response (tonic) and a comparatively fast adapting unit (phasic). According to Finlayson and Lowenstein[2], proprioceptors in the dorsal longitudinal muscles of the abdomen of some saturniid moths consist of modified muscle fibres, and show tonic but not phasic discharges. In *Limulus*, Pringle[3] recorded tonic discharges from proprioceptive nerve endings in the cuticle of the femoro-tibial joint, and obtained phasic responses from more internally situated chordotonal-like organs. Much histological information is available about internal stretch receptors in insects[4], but apart from Hughes's[5] work on abdominal chordotonal organs, their physiological properties are unknown.

The following observations on a stretch receptor in the coxo-trochanteral joint of the leg of the cockroach *Periplaneta americana* L. may be of interest. The anatomical situation and innervation of the chordotonal organs in the second thoracic leg have been studied in our laboratory by Nijenhuis and Dresden[6]. The coxal organs are surrounded by a group of flexor muscles and contain only a few scolopidia; they are stretched by extension of the joint. The largest of the three coxal organs is innervated by six moderate-sized fibres, and the two smaller organs by six small fibres.

Proximal hair plates which might complicate the results were removed, and the activity of the chordotonal organs was then recorded from the nerve (3*B*) with platinum electrodes, a pre-amplifier and oscilloscope. The organs at rest show a fairly constant spontaneous discharge of small amplitude and of frequencies up to about 50 sec.$^{-1}$. Extending the leg in steps produces a low-amplitude discharge, the frequency of which increases with increasing mechanical tension up to a maximum of 100–250 sec.$^{-1}$ (Fig. 1). In the first 15 sec. adaptation is rapid (to 30–50 per cent of the initial discharge frequency), and then becomes slower (Fig. 2); after 10 min. the frequency is still about 1·5 times that of the spontaneous activity in the normal resting position of the leg. The movement itself is accompanied by a considerable discharge, the frequency of these impulses depending on the speed of movement and reaching a maximum of about 250 sec.$^{-1}$. During flexion this activity is completely absent. The amplitude of the slowly-adapting (tonic) discharges seldom exceeds 250 μV.; that of the phasic impulses is generally greater than 500 μV. This difference may be correlated with the presence of smaller and larger chordotonal organs and their corresponding axons. We have been unable to discover the reflex function of these discharges, possibly because of the difficulty of realizing adequate experimental conditions for the functioning of the central nervous system.

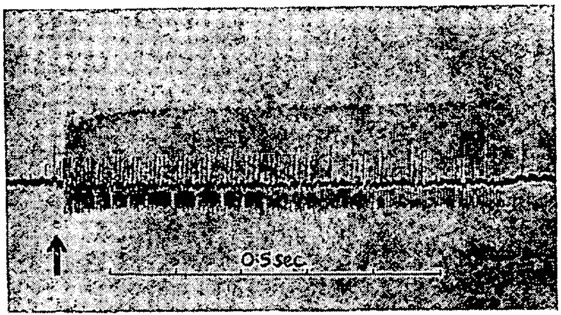

Fig. 3. A high-frequency train of impulses 1 hr. after the administration of 40 μgm. DDT. Movement indicated by the arrow

Toxicological observations have been made with some insecticides, the insects being poisoned by the injection of an emulsion. A high dosage of 30 μgm. lindane (*LD*50 = about 5 μgm.) produces a period of convulsions, followed within one hour by a stage in which the insect becomes almost completely paralysed and seemingly inexcitable. The sense organs, however, appeared to be unaffected, even after three hours. An entirely different result is obtained with DDT. A high dosage of 40 μgm. DDT (*LD*50 = about 25 μgm.) produced marked convulsions which were maintained throughout the experiment. In the first hour high-frequency 'trains' of action potentials (350 sec.$^{-1}$), as described by many authors (for example, Roeder[7]), could be observed both spontaneously and after mechanical stimulation (Fig. 3); the wide range of amplitudes (not illustrated) suggests that all types of fibre are excited. Later there was another remarkable feature of DDT poisoning;

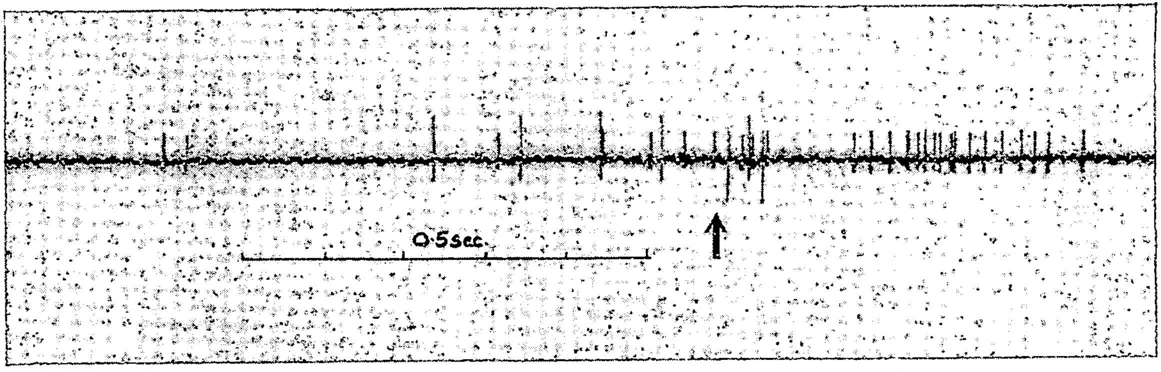

Fig. 4. The same preparation as in Fig. 3, but after 2·5 hr. Movement indicated by the arrow

the continuity and regularity of the tonic discharges was lost and only short trains at low frequency (5–10 sec.$^{-1}$) remained. At this stage the phasic response is reduced to a few impulses (Fig. 4), and the range of amplitudes becomes reduced, showing that there are fewer active fibres.

The preparations usually survived for many hours. The simplicity of the experimental procedure and the regularity of the responses make this preparation a very convenient one for physiological and toxicological investigations.

Direct Determination of the Active Phase of End-Plate Potential

IT is well known that the duration of transmitter action in neuromuscular transmission is very brief, of the order of 4 msec., and prolonged decline of the end-plate potential is due to the slow dissipation of charge along and across the resting membrane[1-4]. The time course of the active phase of the neuromuscular transmission has been calculated by some authors[1,3], but it has not yet been obtained experimentally. In the present investigation the time course of the active phase of the transmitter producing the end-plate potential was recorded by a refined voltage clamp method (the original method was described by Hodgkin *et al.*[5]).

Two microelectrodes filled with 3 *M* potassium chloride were inserted into the end-plate focus of the curarized frog sartorius muscle. One of these electrodes recorded the membrane potential, and the feed-back amplifier regulated the current entering the other electrode in such a way as to hold the membrane potential at the resting value during the neuromuscular transmission. The membrane potential and the current which flowed through the current electrode were recorded with a double-channel oscilloscope. The focus of the end-plate was carefully located with multiple re-insertion of the electrode, and the current electrode was inserted within 50μ of the recording electrode. In order to increase the feed-back factor and also to reduce the capacitative escape of the feed-back current, a low-resistance electrode of about 5–10 MΩ was used especially for the current electrode. Fig. 1*a* shows the end-plate potential without feed-back and Fig. 1*b* the membrane potential clamped at the resting potential with negative feed-back and the feed-back current entering the current electrode during the neuromuscular transmission. The time course of the feed-back current represents the time course of the active phase, without electrotonic dissipation of charge, which produces the end-plate potential.

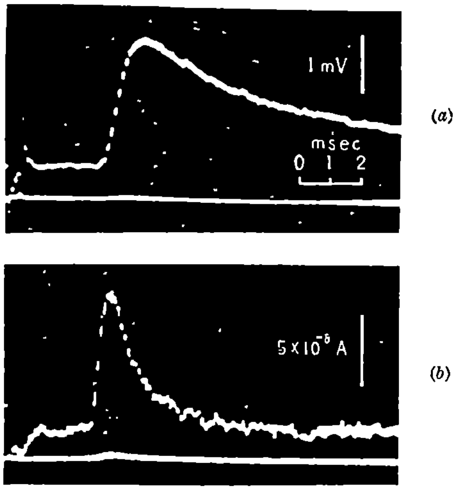

Fig. 1. *a*, End-plate potential recorded intracellularly from a curarized frog muscle; *b*, upper record—feed-back current flowing through the current electrode, so as to clamp the membrane potential at the resting value; lower record—the membrane potential held at the resting level with a voltage clamp method during the neuromuscular transmission. All records were recorded from the same end-plate using the double-channelled oscilloscope

The general time course of the current was very similar to that of the active phase obtained by calculation[1,3]. The duration of rising phase was about 0·5 msec., and the peak to half-decay time was 0·6–0·9 msec., the total duration being 3–4 msec., at 18° C. The time course was prolonged by lowering the temperature or eserinizing the preparation, as will be reported in a later communication.

Abrasion of the Insect Cuticle by Aqueous Suspensions of Small Particles

I HAVE recently had occasion to require a standard or repeatable degree of abrasion of the cuticle of an insect, the larva of *Rhodnius*[1]. It was observed that in regions where excreta containing crystals of uric acid had dried on the surface, the cuticle appeared to be more permeable, suggesting that the drying of suspensions containing solid particles might produce abrasion. This was tested by applying suitable suspensions in distilled water, allowing them to dry in air, removing the particles in a stream of water and then testing for abrasion by exposure to ammoniacal silver hydroxide[2].

Process white (barium sulphate), 'Almicide' (fine crystalline aluminium hydroxide), 'Carborundum' 500, and activated charcoal were used as test materials. In all cases there was extensive abrasion of the surface as revealed by silver staining (Fig. 1). This abrasion was most evident over the crests of the folds in the cuticle, although the particles were deposited also in the depressions. Abrasion was usually

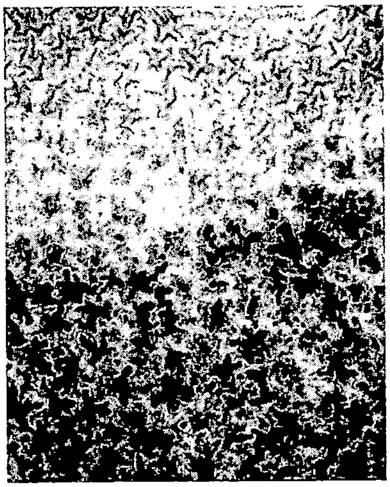

Fig. 1. Cuticle of fifth-stage larva of *Rhodnius*; intact insect immersed for 2 hr. in 5 per cent ammoniacal silver hydroxide. Upper half: normal, unstained. Lower half: area treated with alumina suspension; abrasion of crests of cuticular folds revealed by silver staining

most evident at the periphery of the dried deposit. The number of abraded points was naturally smallest with 'Carborundum' 500, where the particles are the largest. Abrasion does not occur if the powders are carefully applied to the surface in the dry state.

During the drying of these deposits the particles will be subjected to large surface tension forces. As the air replaces the water the particles or aggregates will be forcibly displaced first in one direction and then in another. The resulting abrasion would be expected to affect chiefly the crests of the cuticular folds and the margins of the deposit.

These observations have an obvious bearing on the entry of insecticides when crystals of poisons suspended in water are allowed to dry on the cuticle[3]; for abrasion of the surface facilitates the entry of insecticides[2]. They may also explain the increased loss of water from insects on which suspensions of activated charcoal have dried[4]. Indeed, it was suggested by Holdgate[5] that the increased transpiration observed by Glynn Jones[4] when suspended powders were allowed to dry on the cuticle might be due to abrasion brought about by surface forces.

Determination of Glucose and Lævulose in Body-Fluids

THE current methods for the determination of monosaccharides in blood and other body-fluids are comparatively complicated and time-consuming. Moreover, they are more or less non-specific.

We have devised methods which are specially aimed at specific determination of blood glucose but which can also be used for a separate determination of lævulose. These methods employ condensation reactions between monosaccharides and certain aromatic amines to give coloured products in nearly water-free acid solutions[1]. The colours are characteristic and very suitable for colorimetry. Two new methods are described here: method *A*, using *p*-aminobenzoic acid as coupling reagent for the condensation; and method *B*, using *m*-aminophenol. These methods probably give principally different condensation products. *p*-Aminobenzoic acid reacts with aldosugars, such as glucose and galactose, and only to a small extent with ketosugars such as lævulose. *m*-Aminophenol reacts with both aldosugars and ketosugars.

(*a*) *Blood.* 0·1 ml. blood is pipetted into 1 ml. of a 5 per cent solution (method *A*) or 3 per cent solution (method *B*) of trichloracetic acid in water in a small centrifuge tube. The mixture is centrifuged.

Method *A*. 0·2 ml. of the clear supernatant is mixed in a 'Pyrex' test-tube with 4 ml. of a 5 per cent solution of *p*-aminobenzoic acid in glacial acetic acid. After heating for 15 min. in boiling water the tube is cooled and the absorbance measured against a reagent blank at 4700 A.

Method *B*. 0·1 ml. of the supernatant is mixed with 3 ml. of a 2 per cent solution of *m*-aminophenol in glacial acetic acid. After heating for 30 min. in boiling water the tube is cooled and the absorbance measured against a reagent blank at 5250 A.

(*b*) *Serum.* Precipitation of the proteins is not necessary for method *B*.

Method *B*. 0·01 ml. serum + 3 ml. *m*-aminophenol solution are treated as in *B* above.

(*c*) *Urine.* Method *A*. 0·002 ml. urine (or 0·1 ml. urine diluted 1/50) + 4 ml. *p*-aminobenzoic acid solution are treated as in *A* above.

Method *B*. 0·001 ml. urine (or 0·1 ml. urine diluted 1/100) + 3 ml. *m*-aminophenol solution are treated as in *B* above.

Ultramicropipettes, according to Sanz[2], can be used for the small quantities of urine. Each series of tubes should contain at least two standards of different concentration and one reagent blank.

Method *A* gives absorbances which are directly proportional to the sugar concentration between 50 and 1,200 mgm. glucose (or galactose) per 100 ml. blood or serum and between 0·1 and 6 per cent in urine. The colour is stable for at least three hours. The absorbance of lævulose is about 22 per cent that of glucose.

Method *B* gives absorbances which are proportional to the sugar concentration between 50 and 600 mgm. glucose (or galactose) per 100 ml. blood or serum and between 0·5 and 6 per cent in urine. The colour is stable for at least three hours. The absorbance with lævulose is about 138 per cent that of glucose.

The quality of some of the reagents is of utmost importance to the purity of the colour. The acetic acid must be free of both water and aldehydes, otherwise a false coloration of blank and samples is obtained. The blank must be practically colourless after boiling. The following brands of acetic acid have proved acceptable: 'Analar' p.a., 'Riedel de Haen' p.a., 'Skogen purum' (Skogens Kemiska AB, Kilafors, Sweden), but better results are obtained if the acid is redistilled. Acetic acid from some other manufacturers could not be used even after redistillation. The *p*-aminobenzoic acid causes no trouble: ours is from AB Ferrosan, Malmö, Sweden. It can be used directly, giving linear readings. The *m*-aminophenol at present available commercially is usually impure and has to be re-crystallized from toluene. *m*-Aminophenol, sufficiently pure for direct use, can be ordered from Ferrosan Co., Malmö, Sweden. The reagents must be made fresh every day.

The methods give different reactions with aldosugars and ketosugars, and consequently they can be used for quantitative differentiation between these two groups.

Added in proof. The wave-length at which *p*-aminobenzoic acid gives a linear standard curve and similar readings for the same concentration of glucose in blood and water varies with different brands of glacial acetic acid. As a routine method we definitely prefer method *B*.

Deposition of Glycogen and Changes in some Enzymes in Brain Wounds

IT is well established that areas of fresh brain injuries are surrounded by a concentric zone showing a marked deposition of glycogen[1-3]. In the healthy adult mammalian brain, however, glycogen is scarcely demonstrable by routine histological fixation and staining methods, except for the paraventricular structures[4,5]. In addition to possessing a large amount of rather stable glycogen, the paraventricular structures reveal an evident action of phosphatases[6,7] and relatively slight activity of respiratory enzymes[8,9].

Stab wounds were made in the cerebral cortices of adult rats and the cerebri examined from 6 hr. to 21 days after the operations. For staining glycogen, animals were subjected to rapid intravascular perfusion fixation and the sections were stained with the lead tetraacetate–Schiff method[4]. (This method brought out not only glycogen in the paraventricular structures and in the brain wounds but also labile glycogen present in other portions of the brain.) Fresh frozen sections were used for histochemical demonstration of acid and alkaline phosphatases, 5-nucleotidase, phosphorylase, succinic dehydrogenase and cytochrome oxidase[3].

The lead tetraacetate–Schiff method, applied to paraffin sections of the brain, stains the mucopolysaccharide of the ground substance as well as glycogen similarly to the periodic acid–Schiff method. The stab wounds were surrounded by two distinct zones in 6 hr.–3 days, the inner Schiff-negative or slightly positive zone, deprived of ground substance, and the outer Schiff-positive glycogen-containing zone[2,3] (Fig. 1). After 3 days the inner zone began to diminish in extent and disappeared in 10 days. The outer zone showed moderate glycogen deposition in the intercellular ground substance, glial cells and capillary walls in 6 hr. The zone revealed the maximal glycogen accumulation at 3 days and was followed by a gradual decrease, reaching normal conditions in 14 days. In accordance with the result for glycogen, the outer glycogen-containing zone exhibited a gradual increase in activity of both phosphorylase (Fig. 2) and alkaline phosphatase (Fig. 3) for a period of three days in the intercellular ground substance and capillary walls. Afterwards it was followed by a diminution of both enzyme reactions. The same area showed, however, a slight decrease of succinic dehydrogenase activity (Fig. 4) from 1 to 3 days and subsequent gradual recovery. The reduced reaction could be estimated from the decrease in diformazan granules of smaller size compared with those in the adjoining healthy brain tissues (Fig. 4). The inner layer, deprived of mucopolysaccharide, showed a general decrease in activity of most enzymes tested, excepting a slight increment of 5-nucleotidase and acid phosphatase. With recovery of the wounds, the activity of all enzymes tested in the inner layer was restored to normal conditions. From about 7 days onwards edges of the wounds began to adhere to each other. The adhered linear portion revealed marked amounts of mucopolysaccharide and small amounts of glycogen granules. There were also increases in activity of alkaline and acid phosphatases, 5-nucleotidase and phosphorylase and a reduction of respiratory enzymes.

From these results it is clear that the glycogen deposition in the walls of the brain wounds is accompanied by the concomitant increase in activity of phosphorylase and alkaline phosphatase, and by a slight decrease in succinic dehydrogenase activity. It is suggested by several investigators[10,11] that glycogen deposition may be correlated with a poor oxygen supply or a high anaerobic metabolism. Friede[12] expressed a similar opinion that an increment of glycogen in the brain may be an indication

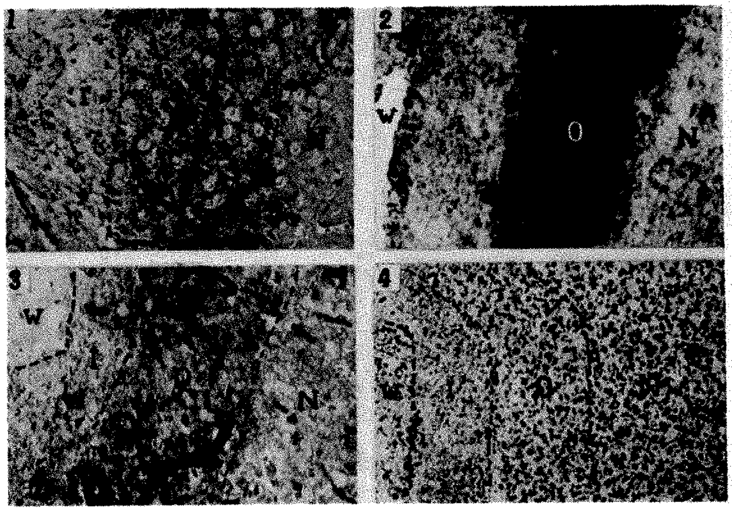

Fig. 1. The lead tetraacetate–Schiff method. Marked deposition of glycogen is observed in the outer layer, which occurs in the neuroglial cells, intercellular ground substance and capillary walls. The inner zone shows a decreased staining. × 125. Fig. 2. Takeuchi–Kuriaki's method for phosphorylase using iodine reaction. Enzyme activity is shown in the outer zone. × 150. Fig. 3. of lowered metabolic rate. Our histochemical observations lead us to suppose that glycogen accumulation, at least in brain wounds, may be correlated with the decreased oxidative metabolism and possibly with prevailing anaerobic glycolysis in the same localities. Apart from somewhat stable glycogen, either in the paraventricular structures or in brain wounds, adult mammalian brains contain variable amounts of labile glycogen, which are demonstrable only after intra-vital perfusion fixation. This labile glycogen co-exists with some respiratory enzymes[4,9]. The probable presence of at least two kinds of glycogen in the brain seems to be comparable with the results on the heart muscle and conducting system reported by Schiebler[13].

Clearing Action of Lysolecithin

RECENT communications[1,2] indicate the growing interest in the properties of lysolecithin. Its clearing action on lecithin sols is remarkable, and mixed sols of lecithin and lysolecithin show an interesting viscosity maximum[3]. The lyso-compound has a considerable effect on the stability of lecithin sols in the presence of salts[3]. Neumann and Habermann point out[2] that the formation of lysolecithin *in vivo* could provide a mechanism for changes in cell membrane permeability.

In these laboratories, we are at present studying the physical properties of lysolecithin sols. Diffusion measurements indicate that the aqueous sols contain large micelles consisting of about 273 molecules of the monomer[4]. These large micelles can incorporate lecithin, and our diffusion measurements with mixed sols of the two phosphatides indicate that the mixed micelles are very much larger than those of pure lysolecithin.

The surface activity of lysolecithin is very high; 10^{-4} per cent wt./vol. in water gives a surface tension (Saunders, L., and Robinson, N., unpublished) of 66 dyne $cm.^{-1}$ at 20° C. It is this combination of high surface activity and large micelle size which makes lysolecithin so effective as a clearing agent for lipid sols.

By Hanahan's method[5], we have made batches of up to 15 gm. of lysolecithin, using Russell viper venom, for the gift of which we are indebted to Dr. A. C. White of the Wellcome Research Laboratories, Beckenham. However, we have found that the product does not give a clear solution in warm ethanol. Prolonged spinning of this warm solution in a high-speed centrifuge gave a residue of weight similar to the weight of venom used in the preparation. We therefore recommend that lysolecithin should be recrystallized several times from warm ethanol, clarifying the warm solution each time[3]. If this is not done, the product will contain traces of venom which will confuse the results of experiments in which the lysolecithin is brought into contact with lecithin sols.

The final product is a white solid, of crystalline appearance, which shows a parallel extinction under the polarizing microscope.

Relative Distribution of the Mitochondria in the Two Types of Fibres in the Pectoralis Major Muscle of the Pigeon

IT has been noted that the pectoralis major muscle of the pigeon consists of two types of fibres, one of them a white, broad and glycogen-loaded variety, and the other red, narrow and fat-loaded[1], and that the lipase activity is much greater in the latter than in the former[2]. Recent studies conducted in our laboratories[3,4] suggest the presence of a well-organized fatty acid oxidation system in the breast muscle of flying birds. Since the mitochondria are known to be the seat of oxidative processes, it was thought desirable to study the relative distribution of the mitochondria in the two types of fibres in the pectoralis major muscle of the pigeon.

For the demonstration of mitochondria, Altmann's method, as described by Gray[5], was adopted. On observing the sections under oil immersion, mitochondria were found to be mainly located in the narrow fibres and extremely sparse in the broad ones. Chappell and Perry[6] reported that mitochondria in the breast muscle of pigeon constitute about 20 per cent of the total nitrogen of the muscle. Our work shows that the broad fibres, which make up not less than one-fifth the volume of the muscle, are poor in mitochondria. Evidently the main bulk of mitochondria obtained by Chappell and Perry must have come from the narrow fibres.

Studies on the cyclophorase preparation of skeletal muscle by Paul and Sterling[7] show that there exists a correlation between granule count and oxidative activity. Chappell and Perry[6] correlated the low oxidative activity of the rabbit muscle suspension with the low granule content, and suggested that this tissue (rabbit muscle) must be largely anaerobic in function.

From all these observations it is evident that the pigeon breast muscle is made up of two distinct components the morphological characteristics of which seem to be correlated with function. With the poor mitochondrial content associated with the high glycogen-load, lack of myoglobin and smaller surface area, the white broad fibres seem to be well equipped largely for functioning anaerobically. On the other hand, the high mitochondrial content, together with the large store of fat, greater lipase activity, the presence of myoglobin and greater surface area afforded in the narrow fibres, suggests that they have a well-organized oxidative system. Further work towards a clearer understanding of the potentialities of these two distinct types of fibre and their mitochondria is in progress.

One of us (R. M. N.) is indebted to the Government of India for the award of a Senior Research Scholarship, which made this work possible.

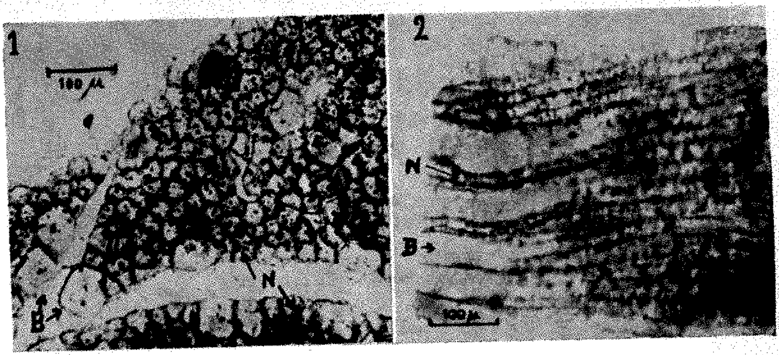

Photomicrographs of (1) a transverse and (2) an oblique section of the pectoralis major muscle of the pigeon showing the disposition of lipase. *B*, broad fibres; *N*, narrow fibres

Histochemical Demonstration of Lipase Activity in the Pectoralis Major Muscle of the Pigeon

Our earlier observation that the pigeon breast muscle contains a lipase[1] has led to the present attempt to demonstrate its presence in this muscle using histochemical methods. The 'Tween' method of Gomori[2] was chosen for the purpose. The substrate used was 'Tween 80' (Atlas). The incubation medium contained 2 ml. 10 per cent calcium chloride, 2 ml. 5 per cent 'Tween 80', 5 ml. bicarbonate buffer[3] of *p*H 8·4, 40 ml. distilled water and a crystal of thymol as preservative. The mixture was kept overnight in an oven at 40° C. and the precipitate formed was filtered off before use. Sections were incubated for 10–12 hr. at 40° C., which is the optimum temperature for this lipase[1]. Parallel experiments were run with sections of pancreas of the same animal for comparison and confirmation of the results. It was noted that acetone destroyed the lipase, and experiments with paraffin sections of tissue fixed in acetone yielded negative results.

A very simple method of preparing sections was adopted and was found to be highly satisfactory. The tissue was cut out immediately after decapitating the animal and placed over ice in the deep freeze of a refrigerator; it was frozen hard in less than half an hour, and without removing it from the deep freeze it was trimmed to shape and thin sections cut with the aid of a cold, sharp razor blade and transferred to an albuminated slide by means of a cold needle. Very thin sections without any appreciable loss of the enzyme in them could thus be obtained. After drying at room temperature to ensure adhesion, the sections were fixed for 16 hr. in cold (4° C.) 6 per cent formalin neutralized with phosphate[4]. They were then washed in running water for about an hour, washed with distilled water and incubated in the above incubation medium. The rest of the procedure was the same as described by Pearse[4]. Since the fibres were stained brown after treatment with ammonium sulphide, the sections were differentiated by treatment with a few drops of hydrogen peroxide in a Coplin jar of 70 per cent alcohol for a few seconds. The sections were not counterstained. Sections which were boiled for 10 min. were used as controls.

Fig. 1 shows the cross-section of a part of the pectoralis major muscle of the pigeon (*Columba livia*) in which the two types of fibres, a narrow and a broad variety, as described by George and Naik[5,6], are clearly discernible. The dark spots in the photograph represent the brownish black precipitate of lead sulphide. It can be seen that the precipitate is abundant in the fat-loaded narrow fibres, whereas the glycogen-loaded broad fibres contain very little. Control sections do not show any precipitate. It is therefore inferred that in the pigeon breast muscle the lipase occurs mostly in the narrow fibres. However, the occurrence of a few grains of the precipitate in the broad fibres is not convincing evidence that they are formed in the same fibres; study of a large number of sections indicates that these granules in the broad fibres are the result of diffusion of products of hydrolysis from the narrow fibres. Fig. 2, showing an oblique section of the muscle giving the longitudinal aspect of the two types of fibres, shows large areas of the broad fibres devoid of these precipitates. This supports the view that lipase is confined, by and large, to the narrow fibres, and very little, if any, occurs in the broad fibres. By contrast, in the pancreas, where lipase is known to be present in large amounts, the precipitate was found to be thickly dispersed throughout the section.

Separation of Bull Spermatozoa carrying *X*- and *Y*-Chromosomes by Counter-Streaming Centrifugation

EXPERIMENTS[1] in which a small fraction (1/20–1/15) of the most easily sedimenting spermatozoa, separated by counter-streaming centrifugation, were used for inseminations gave the unexpected result that the 11 calves obtained from 23 first inseminations were all males. Recent experiments on a larger scale with the same technique have now been performed on semen from 10 different bulls. Whereas in the earlier experiments 1,100 r.p.m. was used, the separation in seven of the present experiments was performed at the same velocity and in eight at 1,000 r.p.m.

The total number of first inseminations with separated spermatozoa was 142, resulting in 63 calves (fertility 44·4 per cent). Compared with the fertility (60·5 per cent) of the corresponding control group (104 pregnancies from 172 first inseminations) this figure is rather low ($\chi^2 = 8{\cdot}26$, $P < 0{\cdot}01$). Of the 63 calves, 36 were females and 27 males (sex ratio 42·9). The sex ratio of this total group does not deviate significantly from the normal one for cattle (106 : 100)[2]. However, a review of the different experiments reveals a considerable variation in fertility, a high proportion of females being apparently associated with high fertility. Therefore the experiments were pooled in two groups, one with fertilities equal to or more than 50 per cent, and the other with fertilities less than 50 per cent. The fertilities for these two groups, 63·8 and 31·0 per cent, respectively, differ significantly ($\chi^2 = 14{\cdot}99$, $P < 0{\cdot}001$).

Of the calves belonging to the first group 28 were females and 9 males (sex ratio 24·3). The corresponding figures of the second group are 8 and 18 (sex ratio 69·2). Also the sex ratios of these two groups differ significantly ($\chi^2 = 12{\cdot}57$, $P < 0{\cdot}001$). This means that the spermatozoa of certain samples are damaged by the counter-streaming centrifugation, and that thereby the female-determining spermatozoa are more sensitive than the male-determining ones. Most probably the factor causing this damage is mechanical stress. This idea is supported by the fact that two groups of experiments which have been pooled according to the r.p.m. used differ significantly as to fertility (pooled samples separated at 1,000 r.p.m.: 53·6 per cent; pooled samples separated at 1,100 r.p.m.: 35·6 per cent; $\chi^2 = 4{\cdot}66, P = 0{\cdot}05$), the high velocity having decreased the fertility more than the low one.

In the light of the present results, the male predominance in the earlier experiments is more easily understood; the spermatozoa were submitted to 1,100 r.p.m. in these experiments.

The group of pooled experiments, having a fertility equal to or higher than 50 per cent, shows a sex ratio which deviates significantly from the normal one of cattle ($\chi^2 = 9{\cdot}31$, $P < 0{\cdot}01$). It thus seems possible to select viable-determining spermatozoa by running the counter-streaming centrifuge at a moderate speed.

In another series of experiments the spermatozoa most difficult to sediment were isolated at 1,100–1,200 r.p.m., and used for inseminations. Here also the female-determining spermatozoa have been eliminated more frequently than the male-determining ones in connexion with decreased fertility. No accumulation of male-determining spermatozoa could be detected in this fraction.

A more detailed account of this work will be published in *Acta Agriculturae Scandinavica*.

Financial assistance from the Swedish Agricultural Research Council is gratefully acknowledged. I am very much indebted to the A.I. Association of Enköping for allowing me to perform these experiments, and to the chief veterinarian, Dr. T. Svensson, and to Dr. K. Idla for most valuable co-operation. The counter-streaming centrifuge was run by Mr. P.-Å. Lindström. All information on the calves was collected by Miss G. Thelin.

Structural Differentiation in the Nucleoid of Mature Vaccinia Virus

IT has been known for some time that mature virus particles of the pox group contain a brick-shaped central body, or nucleoid, surrounded by an outer layer of protein[1]. The fact that in pepsin-treated particles this nucleoid cannot be hydrolysed by deoxyribonuclease alone, but only by deoxyribonuclease followed by a further pepsin digestion, has been taken as an indication that the nucleoid itself contains protein as well as nucleic acid[2]. However, when mature vaccinia virus particles are examined with the electron microscope in thin sections after either osmium or ethanol–acetic acid fixation, the nucleoid presents a more or less homogeneous appearance[3].

In order to investigate further the nucleoidal structure of this type of virus, samples from pellets of purified vaccinia virus particles were dehydrated and embedded in methacrylate for thin sectioning, after fixation with buffered osmium-sucrose[4,5] at *p*H 7·6 or potassium permanganate[6] at *p*H 7·6, for about 1 hr.

Examination of the osmium-fixed particles served to give a point of departure for the work and confirmed the observations of Peters[3] on the general structure of the mature virus and the homogeneity of its nucleoid.

On the other hand, permanganate-fixed particles, although showing an overall internal arrangement similar to the foregoing, exhibited in addition two new features of interest. First, the outer zone of the virus, lying between the outer double-limiting membrane and the double membrane surrounding the nucleoid, appeared both much narrower and considerably less electron dense than in material fixed with osmium (Fig. 1); it is this zone which is usually considered to consist of the peripheral protein layer of the virus[3]. Secondly, and more important, the brick-shaped nucleoid within its double membrane was found to be strikingly differentiated into an inner and an outer region; the electron density of the former was great and that of the latter was slight (Fig. 1), being very similar in this respect to the peripheral protein layer of the virus. In view of this similarity, it is possible that the less electron-dense region lying within the double membrane surrounding the nucleoid might represent the protein constituent of this part of the virus, the nucleic acid corresponding perhaps to the very electron-dense

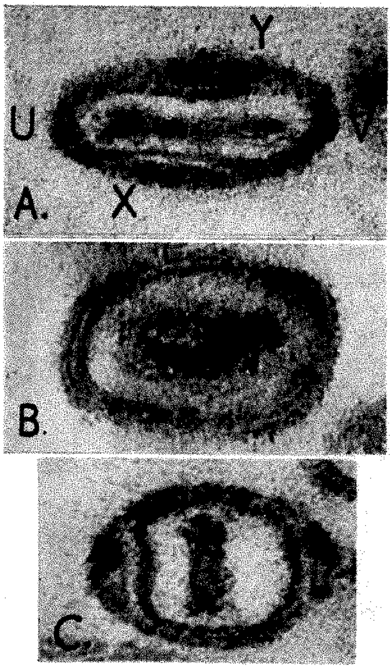

Fig. 1. Thin sections of mature vaccinia virus particles cut in various planes. *A*, Longitudinal section across the shortest dimension of the particle. *B*, Longitudinal section across the longest dimension of the particle; this is at right angles to plane of section *A*, along the line *U*—*V*. *C*, Transverse oblique section along the line *X*—*Y* shown in *A*. Permanganate fixation for about 1 hr. × 120,000. Note in particular the nucleoid within its double membrane showing a central electron-dense disk with a less dense region round about

disk in the centre. However, whatever the answer to this question may ultimately prove to be, the difference in response to permanganate fixation shown by different regions of the nucleoid of mature vaccinia virus particles reflects a definite underlying structural differentiation.

Effect of Glycerol and Low Temperature on Survival of Unfertilized Mouse Eggs

Some unfertilized eggs of the rabbit are still fertilizable subsequent to cooling to temperatures as low as 0° C.[1]. In our attempts to preserve unfertilized mouse eggs at temperatures above and below freezing we have discovered that some of these germ cells survive exposure to −10° C.

The technique of transplanting unfertilized eggs from one female to another was employed in evaluating survival of these cells. Eggs obtained by induced ovulation of immature brown *C*57 females were experimentally treated prior to transplanting them into fertile, mated Bagg Albino (*BALB/c*) recipients where eye colour of the fœtuses served to identify them[2]. The medium used was modified Locke's solution (distilled water, 500 ml.; sodium chloride, 3·38 gm.; calcium chloride, 0·09 gm.; potassium chloride, 0·16 gm.; sodium bicarbonate, 0·05 gm.; dextrose, 0·36 gm.) containing 5 per cent glycerol by volume. Eggs were placed in 0·3 ml. of the medium in each of the 1·5-ml. glass ampoules used as containers. The ampoules, sealed by flame, were then clipped to fibre-glass canes which were immersed in an alcohol bath cooled to −10° C. by pieces of solid carbon dioxide. Glycerol facilitated supercooling and under these conditions the medium was free from ice at −10° C. during the storage periods. The experiment involved the transplantation of 180 eggs into 30 recipients. Results are summarized in Table 1.

Table 1. Survival of Unfertilized Mouse Eggs exposed to −10° C.

Exposure time (hr.)	No. of recipients		No. of transplanted eggs in pregnant recipients		
	Total	Pregnant	Total	Developed	Survival (per cent)
¼	12	8	48	8	17
2	13	7	42	3	5
6	5	4	24	0	0

In the light of current knowledge, the presence of glycerol in a medium designed to favour low-temperature preservation of germ cells seems desirable, perhaps essential. This substance has been found to favour survival of certain mammalian spermatozoa during cooling to and rewarming from sub-freezing temperatures[3]. Although its role as a protective substance against temperature shock in cooling above the freezing temperature is still not evaluated[4], its presence is compatible with survival of unfertilized mouse eggs[2] cooled to 5° C. There is some evidence that exposure of bull spermatozoa to glycerol at 5° C. enhances fertilization following insemination by them[5]. On the contrary, glycerol is said to be responsible for inhibition of fertilization in the fowl during the customary intravaginal insemination of glycerolated semen[6,7]. We recently reported that unfertilized mouse eggs shrank irreversibly at 5° C. in 5 per cent glycerol prior to transplantation, without deleterious effect[2]. According to permeability studies with other cells[8], this would indicate non-penetration by glycerol. We suggested that eggs might re-expand with the penetration of glycerol at the higher temperature in the recipients but this was not investigated. It was decided to ascertain whether or not the presence of glycerol within unfertilized mouse eggs is compatible with their survival as tested by production of normal progeny in the technique of egg transplantation.

Preliminary experiments showed that when eggs are placed in media containing 5 per cent glycerol by volume at 37° C. they shrink initially but quickly re-expand within 8–10 min. Therefore, eggs were exposed to 5 per cent glycerol in modified Locke's solution for 15 min., to ensure penetration, prior to transplantation. Samples of a harvest of eggs from which experimental eggs were obtained were inspected microscopically to check re-expansion phenomenon in each experiment. This phase included 10 recipients and 60 eggs, numbers sufficient for qualitative but not quantitative evaluation as to effect on fertility. Six out of the ten animals became pregnant. Autopsy of these six animals near term revealed that 14 per cent of these glycerol-containing eggs produced apparently normal progeny.

These results establish that: (1) some unfertilized mouse eggs can be cooled to, and stored at, −10° C. for at least 2 hr. in an ice-free medium without loss of functional activity; (2) the presence of glycerol within unfertilized mouse eggs does not prevent their fertilization and subsequent normal embryonic development.

Further details of this work will be included in our subsequent report on temperature shock and hypothermia in unfertilized mouse eggs which will appear elsewhere.

This investigation was supported in part by a research grant (*RG*-4932) from the National Institutes of Health, Public Health Service.

Influence of Time of Mating on the Segregation Ratio of Alleles at the *T* Locus in the House Mouse

THE series of recessive alleles (*t* series) that have been shown to occur at the *T* locus in the house-mouse have aroused considerable interest because of their widespread distribution[1], their effects on embryonic differentiation[2], and their effect on the segregation ratio in males[3,4]. Males that are heterozygous for one *t* allele (that is, $+/t$ or T/t) have been found to sire litters in which the proportion of offspring carrying the *t* allele differs markedly from that expected on the basis of normal Mendelian ratios. In most instances the number of offspring inheriting the *t* allele is greatly in excess of expectation, but with certain *t* alleles the number may be lower than normal. The segregation ratio in females of these genotypes is normal.

Bryson[5] could find no evidence in favour of the suggestion[2] that the segregation ratio abnormality was the result of extra divisions in those spermatids that bore the *t* allele. Other hypotheses that have been put forward[3,6,7] have involved meiotic irregularities or gene conversion; but there is as yet no evidence to support them. Working on the assumption that the mechanism involved in this abnormality was of a physiological rather than a cytological nature and that it came into action only after the sperm had been introduced into the female genital tract, a study was made of the effect of varying the time of coitus in relation to the time of ovulation on the segregation ratio of the alleles *T* and *t*.

Outbred Swiss albino female mice were mated with males of the genotypes T/t^0, T/t^1, T/t^3 and T/t^{12}. Some of the females were caged continuously with a male (three females/male) so that coitus would occur at the normal time (which is about 5 hr. before ovulation[9]); other females were only permitted coitus during a 3-hr. period commencing several hours after the approximate time of ovulation—these are designated 'late-mated'. The mice were kept in a room in which the times of light and dark were automatically controlled so that the time of ovulation could be estimated[8,9]. In mice mated at the normal time, sperm penetration of the eggs begins about 8 hr. after coitus; but in mice mated several hours after ovulation this interval is only about 1 hr.[8]. The normal and late matings were carried on concurrently, that is, males were taken from the 'normal mating' pens for a 3-hr. period each day and placed in the 'late mating' pens. The segregation ratio of *t* and *T* was determined by examining the tails of the new-born offspring: in $+T$ offspring the tail is shortened, but it is normal in $+t$ mice. Many of the females had several litters so, in order to minimize any differences due to the females, they were used in different groups in successive pregnancies.

With each of the eight males tested the proportion of $+t$ offspring was lower after late mating than after mating at the normal time (Table 1), and with one exception the results from each male were highly significant. The mean litter size in the two groups was very similar (about 8·0). The reason for the insignificance of the difference between normal and late mating with male *C* is not clear. It is possibly related to the low fertility of this male—less than half of the females with which he copulated had litters. Two other features of the results should be noted. First, males of the same genotype tended to have very similar segregation ratios and, secondly, the segregation ratio of the T/t^3 male was normal (approximately 1 : 1) in normally mated females, but after late mating the proportion of $+t$ offspring was much reduced ($31 + t : 69 + T$).

These results suggest that the mechanism of the male segregation ratio abnormality in mice carrying a *t* allele has a physiological rather than a cytological basis, and that its time of action is between ejaculation and fertilization. It is not possible at this juncture to be more specific as to the nature of the mechanism. There are many possible hypotheses; but some of them have become unlikely as a result of concurrent studies on the infertility of males carrying two *t* alleles[10]. Further work is in progress. The present results provide evidence in support of the suggestion by earlier workers that the function of a sperm in the female genital tract may be affected by a single genetic locus in such a way that its chances of fertilizing an egg are radically altered. This finding has

TABLE 1. THE MALE SEGREGATION RATIO OF THE ALLELES *t* AND *T* AFTER NORMAL OR LATE MATING

Male	Genotype	Normal mating				Late mating				Significance of difference
		No. of litters	No. of offspring $+t$	No. of offspring $+T$	Ratio	No. of litters	No. of offspring $+t$	No. of offspring $+T$	Ratio

Survival Curves for Male and Female House-Flies (*Musca domestica* L.)

DURING the course of a study on the biochemical changes accompanying ageing in the adult house-fly, the attention of the senior author was directed to the differential longevities of the male and female members of the common house-fly, *M. domestica* L. Paradoxically enough, a search of the literature revealed only scattered and inconclusive information on the longevity of this species under controlled laboratory conditions. Several authors have been cited by Roubaud[1] to the effect that the longevity of the house-fly can be extended to as much as 90 days by exposure to temperatures of 15° C. (59° F.); West, on the other hand[2], states in no convincing terms that the longevity of the house-fly varies from two to three weeks, at most, during the summer and up to three months during the winter months. A side study was therefore undertaken to obtain reliable vital statistics for the male and female members of this species, bred, reared and maintained under standardized laboratory conditions. This report will summarize briefly one phase of this study to be published, *in extenso*, at a later date.

The flies studied represent offspring from many generations of inbreeding of (standard laboratory strain) *NAIDM* flies from the Technical Development Laboratories of the United States Public Health Service (through the kind co-operation of Dr. Albert S. Perry). Results summarized in this communication cover more than 4,000 members of each sex (more than 8,500 flies in all), through nine successive generations; all were maintained, bred and reared (and permitted to age) at 80° F. and 45 per cent relative humidity in our laboratory as described earlier[3]. Eggs were collected from a standard medium when the parents were 4½–5 days old. Offspring were reared on this medium[3] and, under these conditions, emerged as adults exactly 14 days after the first appearance of the parent flies. Parents, as well as ageing flies, were maintained on a powdered whole-milk, sucrose and water diet (*ad libitum*) in bronze screen cages 7½ in. × 7½ in. × 16 in., under temperature and humidity conditions indicated above, in numbers of 150–200 of each sex per cage.

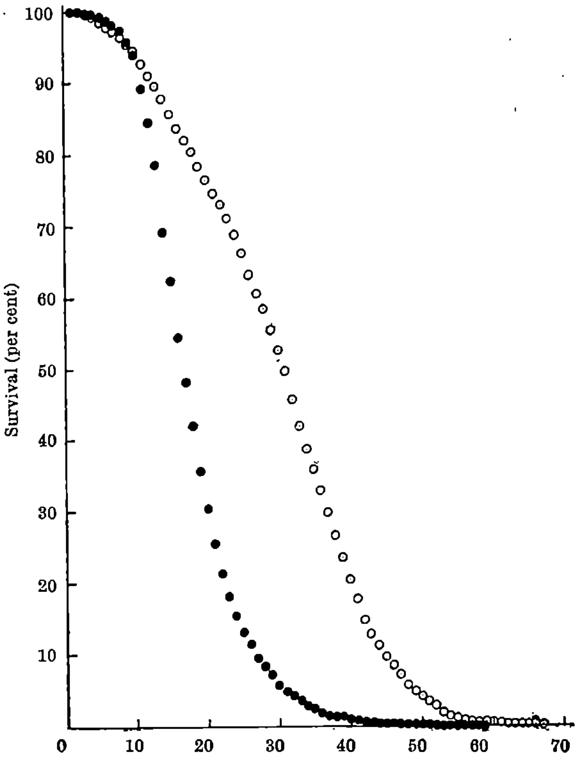

Fig. 1. Survival curves of male and female house-flies. ●, Males; O, females

Fig. 1 shows the survival curves for each sex. These clearly suggest a typical, rectangular form of survival curve representative of animal populations showing senescence (that is, slow rate of death of youthful members of the population followed by an acceleration of mortality during a specific period of the life-history). However, during the final days of adult life this species exhibits a logarithmic-like survival curve with a markedly retarded rate of dying off (40–60 days for the male and 55–70 days for the female). The marked difference in average and maximum longevities of the two sexes is apparent from an examination of the two curves. Thus, about 90 per cent of the males die between ten and thirty days of age, whereas the females die off to the same extent between the tenth and fiftieth day of adult life. What had been observed earlier for only 600 pairs of flies[3] has held true for more than 4,000 flies of each sex through nine successive generations; namely, that at thirty days of age 50 per cent of the females have survived; by the end of this same period of time only about 5 per cent of the males are still alive (indeed, 50 per cent mortality for males occurs at about 16 days of age). In actual longevity figures, males had a mean longevity of 17·4 and a maximum of 54 days; females had a mean longevity of 29·4 days and a maximum of 63 days. Such data clearly confirm the rather widespread occurrence of higher female longevity in animal species discussed elsewhere by Hamilton[4] and Rockstein[3].

This investigation was supported in part by a research grant (*USPHS* No. H-3206) from the National Institutes of Health of the United States Public Health Service.

Pattern of Humus Decomposition in East African Soils

Humus decomposition under bare fallow has now been measured during five successive wet and dry seasons. Soil samples were taken periodically (about once a week during the wet season) and put in the macro-respirometer[1]. The average daily rate of decomposition for the following two days was taken as a comparative measure of the rate at the time of sampling. Using this technique it was found that a relatively high and similar rate of decomposition occurred at the start of each wet period but fell rapidly as uniform moist conditions continued (for example, from 12 mgm. carbon per day at the start of the rains to 4 mgm. three to four weeks later with a soil containing about 6 per cent carbon). Decomposition during the intermediate dry periods was almost negligible.

This simple pattern of composition is of fundamental importance. Since decomposition involves nitrate production it puts soil nitrogen availability on a more predictable basis and emphasizes the importance of timing in planting. This should be done before the start of the rains, or as soon after as possible, when nitrate production is at a maximum, rather than later, when production is much slower and losses of nitrate produced earlier may have occurred through leaching. The pattern also shows that humus decomposition proceeds spasmodically according to the drying and wetting cycle and involves, on each occasion, the rapid decomposition of discrete amounts of humus rather than the slow decomposition of the humus fraction as a whole (see below). An appreciation of this behaviour, and the slow rate of decomposition which may be reached under steady moist conditions, should be of value in work involving humus depletion and build-up. The persistence of this behaviour has been demonstrated in laboratory experiments with the same soil. After forty successive oven-drying and rewettings, with decomposition after each rewetting, the flush of decomposition still occurs, but is declining in magnitude as the reserve of decomposable organic material gets less. So far about 35 per cent of the total soil carbon has been decomposed in this way.

Recent work has shown that while an air-dry soil saturated with different bases gave very different amounts of soluble organic material (10 gm. soil extracted with 40 ml. water), the magnitudes of decomposition (100 gm. soil at field capacity) were almost identical. Similar results, but of greater magnitude, were obtained with the oven-dry soils.

	Air-dry			Oven-dry		
	Na	K	Mg	Na	K	Mg
mgm. organic nitrogen/ 10 ml. extract	0·44	0·26	0·12	0·43	0·40	0·20
mgm. carbon decomposed in 16 days	77·7	77·7	76·4	113·9	120·6	123·3
*p*H	6·3	6·6	7·1	6·3	6·8	6·9

Evidently decomposition involves the humus itself, is little affected by the base present and is not dependent on the preliminary solution of organic material. It appears from this, and further evidence to be published elsewhere, that the drying effect is due almost entirely to its influence on the microbial population. In this respect the uniform pattern of decomposition following each successive drying and rewetting is noteworthy. Since there is ample available substrate, as shown by the frequency with which the drying effect occurs, the rapid fall-off in the rate of decomposition after each rewetting may be due to the development of unfavourable conditions. Alternatively, the same bacterial culture cycle may follow each re-wetting, with high metabolic and enzyme activity during the early phase (characterized by high uptake of oxygen, evolution of carbon dioxide and production of ammonia) falling off during the stationary phase and period of decline. Heat activation of spores may also be involved, and these possibilities are being investigated.

This repetitive behaviour of humus decomposition emphasizes the importance of the wetting and drying cycle in soil fertility. This is particularly marked with nitrate production but other elements such as bases and phosphorus are similarly affected[2]. The behaviour of the soil as regards nutrient supply is clearly very different at the start of the rains from what it is later on, and in soil fertility studies this dynamic aspect of nutrient supply must be considered in conjunction with soil data obtained by conventional methods of analysis.

Effect of Carbon Dioxide on Multiplication of *Fusarium* in Soil

Numerous studies have been made on the effects of carbon dioxide on fungal growth in pure culture, and on substrates other than soil. Since soil is the natural habitat of many fungi, and frequently has carbon dioxide-levels exceeding that present in normal air, it is important that effects of carbon dioxide-enriched air on fungal behaviour in soil be investigated. With the exception of work by Lundegårdh[1] using sterile soil and *Fusarium* species, there is little information available on the effects of carbon dioxide on fungal behaviour in soil. Recently, techniques have been developed[2] for studying *Fusarium* multiplication in natural soil, as indicated by sporulation and increase in number of colonies on soil dilution plates. It was found that carbon dioxide at levels of 2–25 per cent in air for 16–42 hr. frequently stimulated multiplication of *Fusarium oxysporum* f. *cubense*[3]. Studies were initiated with other *Fusarium* species and with carbon-14 dioxide to determine the action of carbon dioxide in stimulating *Fusarium* multiplication. The soil-plate technique[2] was used for studying the effect of carbon dioxide tension on *Fusarium* population as determined by soil dilution plating.

Certain *Fusarium* species in artificially infested loam and sandy loam (*p*H 5·6 and 7·4) were exposed for 42 hr. to normal air and air enriched with 4 per cent carbon dioxide, after moistening the soil with a

Table 1. STIMULATION OF MULTIPLICATION OF *Fusarium oxysporum* IN SOIL PLACED IN AIR ENRICHED WITH 4 PER CENT CARBON DIOXIDE

(Average *Fusarium* colonies per ml. of 1 : 1,000 soil dilution)

	Soil incubated in*	
Culture	Air	Air + 4% CO_2
F. oxysporum f. *lycopersici*	0·8	5·0
F. oxysporum f. *nicotianae*	3·6	18·2
F. oxysporum f. *cucumerinum*	1·6	14·4

* 1 gm. of infested soil moistened with 1 per cent glutamic acid and dilution plates made 42 hr. later.

1 per cent solution of glutamic acid. The species used were : *F. oxysporum* f. *lycopersici*, *F. oxysporum* f. *nicotianae*, *F. oxysporum* f. *cucumerinum*, *F. solani* and *F. roseum*. The forms of *F. oxysporum* were isolated from their respective hosts and *F. solani* and *F. roseum* were isolated from the soil. Results of a representative experiment are shown in Table 1.

In about two-thirds of the experiments performed over a one-year period obvious stimulation of *Fusarium oxysporum* forms occurred in air enriched with 4 per cent carbon dioxide in contrast to normal air.

The behaviour of *F. roseum* and *F. solani* in air enriched with 4 per cent carbon dioxide was more erratic than *F. oxysporum*. In a few instances stimulation was evident but usually there was no stimulation. Apparently these species are less sensitive to the effect of carbon dioxide and/or other soil factors influencing multiplication than *F. oxysporum*. At concentrations up to 25 per cent carbon dioxide in air for 48 hr. there was no evidence of inhibition of survival or multiplication in soil of the *Fusarium* species studied.

To determine if carbon dioxide was being fixed by the fungus, studies were initiated with carbon-14 dioxide and *F. oxysporum* f. *cubense* freshly isolated from diseased bananas. A spore suspension of *F. oxysporum* f. *cubense* was added to 5 ml. of medium in 50 ml. beakers placed in stoppered 920-ml. Mason jars. The medium contained 10 gm. NH_4NO_3, 5 gm. KH_2PO_4, 2·5 gm. $MgSO_4.7H_2O$, 0·02 gm. $FeCl_3.6H_2O$ and 50 gm. sucrose per litre of distilled water, and after autoclaving was at *p*H 4·0. 10–100 μc. of carbon-14 labelled sodium carbonate was then introduced to the bottom of the jars around the beakers and 25 per cent perchloric acid added to release carbon dioxide. The capped jars were sealed with modelling clay. The cultures, thus exposed to radioactive carbon dioxide, formed a large pellicle of fungus in about four days. The resulting pellicles were removed and thoroughly washed with distilled water on filter paper. The washed pellicles were dried at 70° C. in a forced-draft oven, weighed and then ground in a mortar. Each ground pellicle was then thoroughly mixed with sufficient dried banana leaf tissue to make 1 gm., placed in a steel cup planchet and its radioactivity measured. Counts per min. of known quantities of carbon-14 in 1 gm. of banana leaf tissue had previously been determined[4] so that it was possible to estimate the quantity of carbon-14 incorporated by the fungus in the above samples. Two identical experiments were conducted and the results are shown in Table 2.

The total quantity of carbon-14 fixed by the fungus increased with increasing concentration of carbon dioxide, although the dry weight of the fungus (approximately 31 mgm.) differed little in the various concentrations of carbon dioxide studied. The percentage of the total carbon-14 fixed by the fungus, however, decreased slightly with increasing concentration of carbon dioxide in the atmosphere.

Table 2. CARBON DIOXIDE FIXATION BY *Fusarium oxysporum* f. *cubense*

Volume per cent CO_2 in jar	$^{14}CO_2$ (μc.)	Radioactivity in fungus in counts per min. Exp. 1	Exp. 2	Average	Total supplied radioactivity in fungus (per cent)
2·26	100	2,315·8	2,783·7	2,549·8	2·46
1·16	50	1,401·2	1,714·9	1,558·8	3·00
0·48	20	770·6	732·2	751·4	3·62
0·03	0	47·4	34·1	40·8	—

The foregoing results show that carbon dioxide, at concentrations commonly found in the soil atmosphere, can be fixed by mycelium of *F. oxysporum* f. *cubense*. Thus carbon dioxide stimulation of multiplication of the *Fusarium* species studied may be due to participation of carbon dioxide from the soil atmosphere in metabolic processes of the fungus.

Extracellular Products in Pure Cultures of a Brown Alga

USING antibiotics in a way similar to those described by Fish[1] and Spencer[2] for other algae, we have obtained *Ectocarpus confervoides* in bacteria-free uni-algal culture. Bacteria-free cultures of Phaeophyceae (*Waerniella lucifuga* and *Ectocarpus parasitica*) have been grown by Provasoli, McLaughlin and Droop[3], but these do not appear to be particularly suitable for physiological study. It is clearly desirable that studies with pure cultures should be made if exact information about the metabolism of this group of algae is to be obtained.

In natural sea water enriched with nitrate, phosphate, iron and manganese, *E. confervoides* has a mean doubling time, in the early stages of growth, of about one week at 20° C. and a light intensity of 6,000 lux. Growth continues slowly for up to 30 weeks, according to the volume of the cultures, giving final yields of about 0·9 gm. dry weight per litre. In such cultures the medium becomes coloured distinctly yellow-brown after three weeks. Following up this indication, an investigation has been made of the extracellular products liberated by *E. confervoides* in pure culture.

The absorption spectrum, as determined with a 'Unicam *SP* 500' spectrophotometer, of the yellow-brown medium from an 11-week culture, after filtration through a sintered glass funnel of porosity 15–40μ, is shown in Fig. 1, curve *A*. After extraction with ether, material having an absorption maximum at 260 mμ remained in the aqueous phase (Fig. 1, curve *B*). The ether extract was yellow in colour with an absorption maximum in the region of 400 mμ (Fig. 1, curve *C* ; vertical scale × 8 that for curves *A* and *B*).

Filtrate from a 5-week-old culture, containing about 7 mgm. cell nitrogen per litre, after concentration and desalting by a method of electrodialysis, gave a positive reaction with ninhydrin, indicating the presence of about 0·15 mgm. α-amino-nitrogen per litre of the original medium. After hydrolysis with an equal volume of 50/50 concentrated hydrochloric acid and glacial acetic acid for 24 hr. at 105° C., 0·2 mgm. α-amino-nitrogen were found. This suggests that the view of Fogg and Westlake[4], that

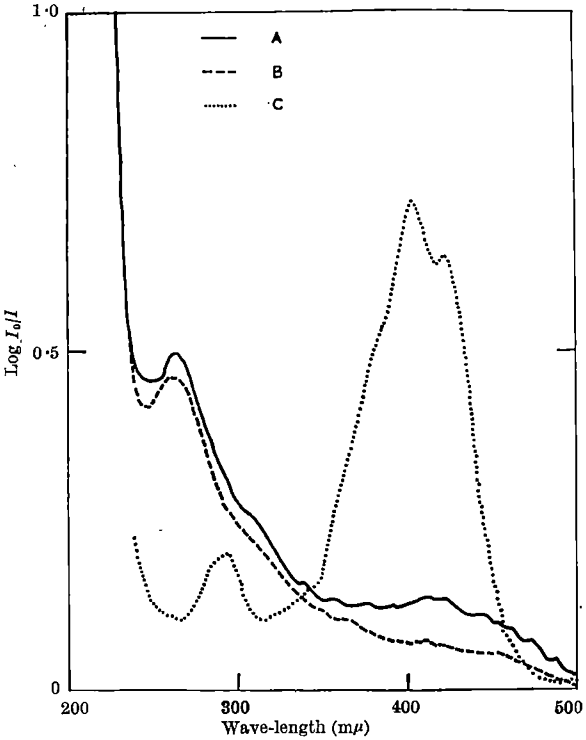

Fig. 1

extracellular nitrogenous compounds are liberated to an appreciable extent by most algae, applies to marine as well as freshwater species. It seems likely that this nitrogenous material is responsible for the absorption at 260 mμ observed in *E. confervoides* media after extraction with ether, but its further characterization has been hampered by the difficulty of desalting the large volumes of sea water required.

Paper partition chromatography, using mixtures of methyl alcohol and toluene, showed the ether-soluble fraction to contain four pigments. In their absorption spectra and ether solubility these resemble carotenoids. It is possible to reconcile this with their solubility in water by supposing that they are protein–carotenoid complexes such as those obtained from the chloroplasts of higher plants by Nishimur and Takamatsu[5].

Separation on a powdered cellulose column gave three well-defined fractions, the first of which appeared to have two components. When attempts were made to transfer these from ether to distilled water it was found that they were readily photo-oxidized when in contact with water and air. However, the pigments appear to be stable in the cultures and in the filtered medium prior to ether extraction, and are also stable when dissolved in ether. This further indicates the presence of a complex in the medium which is broken down on ether extraction.

Spectrophotometric examination of the filtrates from cultures of different ages has shown that the amount of the water-soluble ether-insoluble material absorbing 260 mμ is proportional to the growth of the alga as measured by dry weight. The total amount of yellow ether-soluble material also increases with the age of the culture, but it seems from the less regular relationship that the proportions of the individual pigments liberated vary during the course of growth. It seems likely from this that both types of extracellular product are liberated from healthy cells.

Work directed to the further characterization of these extracellular products of *Ectocarpus* is in progress. Meanwhile, it seems worth recording these results in view of the current interest in dissolved organic substances in natural waters, as discussed by Lucas[6], Saunders[7] and Vallentyne[8]. It is possible that extracellular nitrogenous compounds such as those of *Ectocarpus* contribute to the dissolved organic nitrogenous material present in sea waters, the ecological importance of which as a chelating agent may be considerable. No yellow pigments exactly corresponding with those liberated by *Ectocarpus* appear to have been recorded in sea water, although the absorption spectrum[9] of the 'yellow substance' found in neritic waters by Kalle has some resemblance to that of one of the components of the ether-soluble fraction.

We are grateful to the Development Commission for a grant made to one of us (G. T. B.), which has enabled this research to be carried out.

A Freshwater Mutant of *Balanus amphitrite*

A few species of animals which were known to be marine have become freshwater dwellers. An example of these freshwater mutants is the gastropod *Hydrobia jenkense* which, according to Ellis[1], was known to have been confined to brackish waters until the early part of the last century and is now abundant in freshwater in many parts of Great Britain and seems to be spreading widely in continental Europe.

The limiting ecological factors of the freshwater environment are only survived by mutant types of marine animals which were endowed with proper thermo- and osmo-regulation systems and a totally embryonic development. The absence of such adaptive mutations, or their inaccessibility to freshwater, from whole phyla such as Echinodermata, or whole classes of phyla such as Cephalopoda and Cirripedia, have made their representatives still exclusively marine.

In the north-east of the Nile Delta, some 40 miles south of the mouth of the river, freshwater from the Damietta branch of the Nile is constantly pumped by powerful machines during the floodless season (November–July) through a deep cement-built tank for the irrigation of a large area of land. The machines stop during the flood season (August–October) and the water in the tank falls to the level of the Nile. When the tank was studied for its fauna in

Fig. 1. *Balanus amphitrite* var. *denticulata*. (× 25)

July 1954, the walls and rocky floor were found densely populated with colonies of barnacles. Fixed specimens were identified by Dr. J. P. Harding of the British Museum (Natural History) as *Balanus amphitrite* var. *denticulata* Broch[2]. Broch's specimens, described in 1927, came from the Suez Canal, where the salt beds make the salinity higher than that of the sea. Since then the variety has been found in a number of localities, including the coast of Great Britain. *Balanus amphitrite* is often carried on ships' bottoms.

When the tank was investigated in December of the same year, only dead shells the inner walls of which were stuffed with embryo-like structures were found (Fig. 1). The tank has since been visited at irregular intervals, but so far no live specimens have been recovered.

It is believed that the mutant barnacle is of a seasonal occurrence. It exists only in the presence of favourable environmental conditions and dies when unfavourable conditions prevail, leaving resting embryos which remain dormant until the favourable conditions return. The reason why live specimens ceased to be found is now being investigated.

Microbenthos of the Shore at Whitstable, Kent

WHILE the results of a study conducted in the period September 1953–November 1955 have now been analysed, the inevitable delay in publication makes a summary of the results obtained both of interest and use. The term microbenthos is taken to include all those forms which will pass through a 1-mm. sieve.

The sandy flats studied lie at a gradient of 1/600 and consist of fine sand of average depth 7 cm., overlying London Clay of indeterminate depth. Drainage is such that the shore is covered to a greater or lesser degree by surface water in every exposure period. The microfauna but not the microflora showed marked differences in distribution dependent on differences in the soil grade. The microbenthos exhibited a patchy horizontal distribution, while vertically diatoms, copepods and ostracods were confined or tended to be confined to the surface 4 mm. of soil, nematodes lived in large numbers below this level in the sand, but not in the London Clay, which acted as an effective barrier to further penetration. All groups had a maximum population in the surface 2 mm. of soil.

The fauna here is the richest so far recorded in an unpolluted area, being, in 1955, $5 \cdot 22 \times 10^6$ nematodes per sq. m., $7 \cdot 422 \times 10^5$ ostracods per sq. m. and $4 \cdot 863 \times 10^5$ copepods per sq. m., at the time of their respective seasonal maxima, and the constitution of the microfauna at Whitstable seemed to be markedly different from other recorded microfaunas.

Seasonal changes were investigated at a position on the shore with a 3-hr. exposure period. It was found that the nematodes always dominated the fauna, while the ostracods and copepods only reached a maximum when the nematodes had started to decline. Ostracods dominated the copepods in the autumn, winter and spring months but in summer the copepods were dominant over the ostracods. *Leptocythere pellucida* was the most abundant form of ostracod, while *Asellopsis intermedia* was the most abundant harpacticoid copepod at all times of the year.

The microfauna as a whole showed one seasonal maximum in numbers, the population changes showing a correlation coefficient of $+ 0 \cdot 75$ with the mean sea temperature at the 0·1 per cent level of significance. Not only is the breeding cycle dependent on temperature, but it was found that between 0° and 20° C. activity of the harpacticoid copepods increased, while, in the shore itself, if temperatures fell below a value about 4° C., the microfauna showed a marked downward migration. A positive reaction to light was exhibited by many members of the three major groups; in particular the harpacticoid copepods reacted positively at all light intensities investigated between less than 2- and 2,000-ft. candles.

With the methods used, only the nematodes were found to exhibit a tidal rhythm. All three groups, nematodes, ostracods and copepods, moved actively on the surface during exposure and in the main body of sea water when covered. Some species, both of microflora and microfauna, occurred in considerable numbers in the inshore plankton while other forms occurred exclusively in the shore. Zonation was of the extended nature expected of the microfauna of a shore with such a low gradient as the sandy flats at Whitstable.

Absence of the Diego Blood Group and Abnormal Hæmoglobins in 92 Maoris

RECENT investigations of Mongoloid populations have shown in some of them a high incidence of hæmoglobin *E* and of the Diego blood group. The highest frequencies of hæmoglobin *E* have been found in Siamese, Burmese and north-east Malaysians, and the highest frequencies of the Diego blood group in South American Indians, followed by Japanese, North American Indians and Chinese. Hæmoglobin *H*, although seen in some Greeks and in a Jordanian Arab, has in the majority of the still relatively few observations been found in people of Asiatic Mongoloid origin, notably Chinese and Siamese, and occasionally in Philippinos and Malaysians. Lastly, thalassæmia or Mediterranean anæmia is now known not to be restricted to persons of Mediterranean origin, for the observation of a high incidence in Siamese[1] has been followed by similar reports from other

Asiatic populations, both non-Mongoloid and Mongoloid.

In the Australasian region so far no abnormal hæmoglobins have been found in 166 Australian aboriginals[2] and 56 Melanesians (Horsfall, W. R., and Lehmann, H., unpublished). No example of the Diego blood group has been found in 62 Australian aboriginals, 23 eastern Papuans, 74 natives of New Britain and 80 eastern Polynesians[3].

We have examined 92 Maoris, of whom 65 were not first-degree relations. There is considerable intermarrying and as the people investigated live in a small area it is likely that some of these 65 are also related. The aim has been to obtain a gene pool which represents Maoris without White admixture. 85 belonged to the Tuhoe and 7 to the Arawa tribe. All were examined for the Diego blood group and for hæmoglobins *E* and *H* as well as for other abnormal hæmoglobins which can be detected by the sickling test or by electrophoresis. Hæmoglobin *H* is unstable, and control experiments were made to exclude the possibility that it escaped detection under the conditions of our experiments. In 84 samples a search was made for evidence of thalassæmia by examining the cells morphologically, by determining the alkali-resistant fraction of the hæmoglobin and by searching for an increased proportion of hæmoglobin A_2.

No hæmoglobin *E*, *H* or any other abnormal hæmoglobin, no Diego blood group and no evidence of thalassæmia were found. Our findings distinguish these Maoris from the North and South American Indians so far examined, and from the Siamese, Burmese and Malaysians. It cannot be taken to distinguish them clearly from Indonesians, Dyaks and other South Asian Mongoloids. Hæmoglobin *E* and the Diego blood group have been found at low frequency in some of these populations, but it is more likely that this is due to their mixing with neighbours in whom these characters are common than to represent in them essential racial features. We hope to extend these investigations and to examine in the first instance a tribe in the Ruatoki area in the coming year.

It is noteworthy that the Diego factor has not been found so far, in view of Heyerdahl's theory of the American origin of the Polynesians.

Carbon-14 Dated Palæoliths from Borneo

1957 excavations by the Sarawak Museum at Niah Great Cave, West Borneo, produced a succession of human phases from subsurface Bronze Age through 'Neolithic' polished axes and adzes (to 24 in.), then edge-ground and 'pebble' tools, and below these unworked flakes and blades; deeper again (below 72 in.) crude 'choppers', in the sense lately re-defined by Prof. H. J. Movius[1]. A preliminary report[2] lacked carbon-14 information from the lower levels. Now Prof. Hl. de Vries, of the Physical Laboratory, University of Groningen, Holland, who has kindly carried out all our tests, reports on a charcoal sample from about 100 in.:

GRO. 1339 39,600 ± 1,000 years (1957)

It is not yet possible exactly to co-ordinate crude depths with artefact stratification, owing to unevenness in Niah's enormous human (not geological) deposit. It is clear, however, that we are down into the Palæolithic on an orderly sequence, for the first time in south-east Asia. Other early stone-age finds in this area have been at geological or casually exposed sites, without clearly interrelated animal remains, bone, shell, fire and extraneous stone associations.

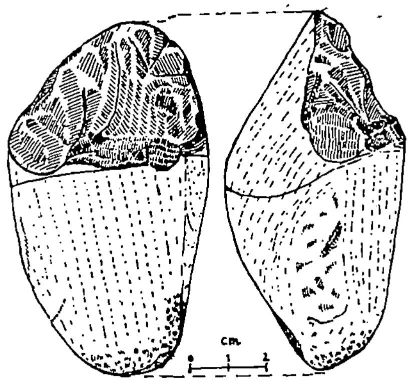

Fig. 1. Stone chopper from below 72 in. Niah Great Cave, Sarawak

The stone tools occurring between *GRO.* 1339 and a previous carbon-14 date (*GRO.* 1158) of 32,630 ± 700[2], are often uniface choppers, with hammer marks on the butts (Fig. 1). These closely parallel some from the 'Soan Culture' of north-west India, as figured by Dr. Kenneth Oakley[3]; five tools found on a gravel terrace in south-east Borneo[4]; and part of a recent collection from west Thailand[5], which I have examined in the National Museum, Bangkok. We should eventually be able to get a clearer idea of the Later Palæolithic in south-east Asia, using Niah stratified material as provisional yardstick, with further excavation in 1958 (thanks to a grant from the Calouste Gulbenkian Foundation of Lisbon[6]). It already seems that more caution should be exercised before attributing crude tools in any general way to the Lower Palæolithic in Asia—as has lately been done for the south-east Borneo pieces[4] and the Malayan 'Tampan'[7]—unless there is supporting evidence beyond the superficial look of the artefacts themselves.

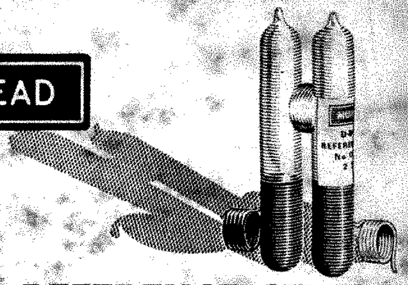
MUIRHEAD



D-845 REFERENCE CELLS

These cells will function under widely varying temperature conditions—be tolerant to a wide range of mounting positions—withstand rough handling and yet maintain an accurate and stable reference voltage. Mounted and unmounted types are available from stock in limited quantities.

SPECIFICATION

E.M.F. 1·0193 volts absolute, subject to manufacturing tolerance of 0·0005 V Unmounted, 0·0002 V Mounted.
Temperature coefficient Does not exceed 5μV/°C over the range 10°—40° C.
Temperature hysteresis Negligible over the normal temperature range.
Internal resistance at 25° C. Average 800 ohms, maximum 1200 ohms.

MOLECULAR WEIGHTS

. . . A quick new way

★ Determinations in 10 minutes.
★ Accuracy 1% with 0.2g samples.
★ Rapidly reaches equilibrium (< 3 minutes)
★ Thermistor sensing for rapid response and high sensitivity.
★ Borosilicate glass parts.
★ Additional equipment not required.
★ Simple to use.
★ Quickly saves its own cost in time gained.

Designed in co-operation with Mr. C. Heitler of Northampton College of Advanced Technology (London).

FORTHCOMING EVENTS

(*Meeting marked with an asterisk * is open to the public*)

Monday, March 17

Institute of Metal Finishing (at the Northampton Polytechnic, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. H. Cann: "Anodes".

Monday, March 17—Tuesday, March 18

Society of Chemical Industry, Pesticides Group (at 14 Belgrave, Square, London, S.W.1), from 5.30 p.m. to 9 p.m. each day—Conversazione—"New Techniques in Pesticide Research".

Tuesday, March 18

Parliamentary and Scientific Committee, General Committee (in Committee Room 12, House of Commons, Westminster, London, S.W.1), at 5.15 p.m.—Discussion on "Space Satellites and Relevant Matters". Opening Speakers: Prof. A. C. B. Lovell, O.B.E., F.R.S., Prof. H. S. W. Massey, F.R.S., and Dr. D. H. Sadler, O.B.E.

Royal Society of Arts, Commonwealth Section (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—The Hon. F. W. Bulcock: "The Pastoral Industry of Australia".

Institute of Physics, Electronics Group (at 47 Belgrave Square, London, S.W.1), at 5.30 p.m.—Annual General Meeting, followed by Mr. L. A. Thomas: "Microwave Ferrites".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Sir John Cockcroft, F.R.S.: James Forrest Lecture.

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Prof. W. E. Curtis, F.R.S.: "Magnetism". (Further lectures on March 19, 25 and 26. Lectures for Sixth Form Boys and Girls from Schools in London and the Home Counties.)

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Discussion on the Technical Committee's Report "Recommended Method of Expressing Electronic Measuring Instrument Characteristics. 1: A.M. or F.M. Signal Generators".

Wednesday, March 19

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2) at 2.30 p.m.—Sir Christopher Hinton, K.B.E., F.R.S.: "Industrial Power of the Future" (Trueman Wood Lecture).

Royal Institute of Chemistry (joint meeting with the London Branch of the Institute of Biology and the London and Home Counties Branch of the Institute of Physics, in the Sir William Beveridge Hall, Senate House, University of London, W.C.1), at 4.30 p.m.—Symposium on "Science and Society". Speakers: Prof. P. M. S. Blackett, F.R.S., Prof. L. T. Hogben, F.R.S., Prof. A. Haddow, Prof. Dame K. Lonsdale, F.R.S. and Mr. Anthony Smith.

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Scientific Papers.

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Sir Robert Shone and Mr. H. R. Fisher: "Industrial Production and Steel Consumption".

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Symposium on "New Human Demands in Industry". Speakers: Mr. Alec Rodger, The Hon. Michael Layton, Mr. R. Peddie and Dr. K. Hutton*.

Society for Analytical Chemistry, Microchemistry Group (in the restaurant room of "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting on "The Microdetermination of C, H and N in the Presence of Interfering Elements (Metals and Non-metals)".

Thursday, March 20

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Meeting for Election of Fellows. 4.30 p.m.—Mr. L. Rotherham: "Atomic Energy Authority Industrial Group Research Organization (Dounreay Reactor)".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—General Meeting.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. N. Jacobson: "Representation Theory for Jordan Algebras".

Institution of Mechanical Engineers, Lubrication Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "How to Bridge the Gap between Theory and Practice in Lubrication".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. G. M. Dormon and Mr. A. W. Jarman: "Some Factors Influencing the Behaviour of Bitumen Road Surfacings".

Scientific Film Association, Sciences Committee (in the Mezzanine Cinema, Shell-Mex House, Strand, London, W.C.2), at 6.30 p.m.—Meeting on "Recent Development in Research Film". Chairman: Dr. R. H. Brown, M.A.

Royal Photographic Society (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Dr. B. H. Crawford and Dr. J. M. Burch: "The Use of Colloidal Photographic Emulsions in the preparation of Interference Filters and Diffraction Gratings".

Royal Society of Tropical Medicine and Hygiene (at the Royal Army Medical College, Millbank, London, S.W.1), at 7.30 p.m.—Laboratory Meeting. Chairman: Brigadier J. S. K. Boyd, O.B.E., F.R.S.

British Institute of Radiology, incorporated with the Röntgen Society (at 32 Welbeck Street, London, W.1), at 8 p.m.—Dr. L. F. Lamerton: "An Examination of the Clinical and Experimental Data relating to Possible Hazard to the Individual of Small Doses of Radiation" (Presidential Address).

Friday, March 21

Faculty of Radiologists (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 4.45 p.m.—Meeting on "Medical Problems associated with Applied Atomic Energy". Speakers: Dr. J. F. Loutit, Dr. A. S. McLean and Dr. J. D. Abbatt.

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Mr. E. J. Dickie, M.B.E.: "The Effective Utilization of Airspace".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. Ekhart Schmidt: "High-Speed High-Performance Diesel Engines—Their Development and Application" (James Clayton Lecture).

Royal Photographic Society (joint meeting with the Association of Printing Technologists, in the Lecture Theatre of the Science Museum, Exhibition Road, London, S.W.7), at 7.15 p.m.—Mr. M. Hepher: "Three Colour Lithography for Short Runs".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. Cyril Dean Darlington, F.R.S.: "The Control of Evolution in Man".

Saturday, March 22

British Social Biology Council (at Victoria Hall (North), Bloomsbury Square, London, W.C.1), at 10 a.m.—Conference on "The Education of Scientists".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (qualified in either pure or applied mathematics) in Mathematics—The Registrar, University College of North Staffordshire, Keele, Staffs (March 21).

Lecturer or Senior Lecturer (male, British, with an honours degree in electrical engineering) in the Physics and Electrical Engineering Department—The Director of Studies, Royal Naval College, Greenwich, London, S.E.10 (March 21).

Patent Officers (with an honours degree in science or engineering or equivalent qualifications, and preferably some patent experience) at the U.K.A.E.A. London Office and the Research Establishment at Harwell—The Establishment Officer, United Kingdom Atomic Energy Authority, 11 Charles II Street, London, S.W.1 (March 21).

Lecturer or Assistant Lecturer in Plant Physiology (with special reference to metabolism and plant biochemistry)—The Secretary and Registrar, The University, Southampton (March 24).

Research Officer (veterinary surgeon, preferably with postgraduate laboratory experience) at the Farm Livestock Research Centre, Animal Health Trust, Stock, Essex, to specialize in diseases of pigs—The Scientific Director, Animal Health Trust, 14 Ashley Place, London, S.W.1 (March 24).

Guide Lecturer (with a university degree or equivalent qualification in geology, and preferably lecturing or teaching experience) at the Geological Museum, London—Civil Service Commission, 30 Old Burlington Street, London, W.1, quoting Ref. No. S/4817/58 (March 27).

Chemist or Biochemist (with a good honours degree in chemistry or biochemistry) in the Department of Plant Cell Biology, to use and develop ultramicrochemical techniques—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford, Herts (March 29).

Physical Chemist or Biochemist, for research work on special derivatives of viruses and on the preparation of virus crystals in conjunction with a team studying the structure of viruses by physical methods—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (March 29).

Senior Scientific Officer (with a first- or second-class honours degree in civil engineering or equivalent) at the Building Research Station (D.S.I.R.), Garston, Herts, for research on engineering design and construction of nuclear power plants, particularly in concrete and reinforced concrete—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting R.609/7A (March 29).

Assistant Algologist (with a degree in botany) at the Windermere Laboratory, for research in freshwater algology—The Director, Freshwater Biological Association, The Ferry House, Ambleside, Westmorland (March 31).

Imperial Chemical Industries Fellows (preferably with the degree of Ph.D. or equivalent research experience), to carry out original research in Chemistry or Physics for a period not exceeding three years—The Registrar, University College of North Staffordshire, Keele, Staffs (March 31).

University Demonstrator in Organic Chemistry—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge (April 2).

Zoologist (man, with a good honours degree and preferably postgraduate experience in marine ecology), to join, and eventually to lead, a team studying plankton in relation to the herring, and duties will include occasional work at sea in fishing vessels and research ships—The Officer-in-Charge, Oceanographic Laboratory, Scottish Marine Biological Association, 78 Craighall Road, Edinburgh 6 (April 5).

Chief Technician in the Department of Physics, University College of Ghana—The Assistant Registrar (London), University College of Ghana, 29 Tavistock Square, London, W.C.1 (April 10).

Assistant Lecturer (suitably qualified graduate in chemistry or agricultural chemistry) in Chemistry—The Registrar, Wye College (University of London), near Ashford, Kent (April 12).

Electronics Technician (with a wide general knowledge of electronics, an interest in instrumentation, an inventive mind and the ability to accept responsibility) in the Department of Chemistry, for duties which will include the development and maintenance of special equipment for teaching and research—The Registrar, The Manchester College of Science and Technology, Manchester 1 (April 12).

Research Fellow and a Research Demonstrator in the Department of Chemistry—The Registrar, University College, Singleton Park, Swansea (April 12).

Research Student (graduate, preferably with qualifications in physical geography) in the Coastal Geography of Roman Britain, centred initially on the Thames Estuary—The Director and Secretary, Royal Geographical Society, 1 Kensington Gore, London, S.W.7 (April 14).

Lecturer in Mathematics, and a Lecturer in Philosophy at Acadia University, Wolfville, Nova Scotia, Canada—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (April 15).

Assistant in the Zoology Department and Gatty Marine Laboratory of St. Salvator's College—The Joint Clerk to the University Court, College Gate, St. Andrews (April 16).

Assistant Lecturer in Social Anthropology—The Secretary, London School of Economics and Political Science, Houghton Street, London, W.C.2 (April 16).

Imperial Chemical Industries Research Fellows in Chemistry, Engineering, Pharmacology or Physics—Joint Clerk to the University Court, College Gate, St. Andrews (April 19).

Technician in the Department of Physiology, University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 20).

Chair of Education, with special reference to education in tropical areas tenable at the Institute of Education—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 23).

Walter Myer and Everett Dutton Chair of Parasitology and Entomology—The Registrar, The University, Liverpool (April 26).

Chair of Geography—The Registrar, The University, Hull (April 30).

Research Fellow in the Department of Nuclear Physics, Research School of Physical Sciences, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 30).

English Electric Research Fellow for postgraduate research into the problems of vibration or stability and control of aircraft—The Warden, The College of Aeronautics, Cranfield, Bletchley, Bucks (May 1).

Mathematicians (2) (preferably with a Ph.D. degree in mathematics)—G. R. Magee, Department of Mathematics, University of Western Ontario, London, Ontario, Canada (May 1).

Professor (with high academic qualifications in science and experience in teaching or research) of Soil Science at Canterbury Agricultural College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, June 30).

Entomologist (under 35 years of age, a university degree (preferably honours) in entomology or zoology and postgraduate experience in applied entomology) in the Tsetse Control Department, Uganda, to conduct investigations into tsetse distribution and ecology in the field; plan and supervise tsetse surveys and control; and train junior staff—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.77/9/02.

Instructors and Assistant Professors (with the Ph.D. degree, or equivalent, in inorganic or physical chemistry) in the Department of Chemistry—Prof. C. A. McDowell, Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada.

Lecturer (preferably qualified in some branch of applied physics) in Physics in the Department of Natural Philosophy—The Secretary, Royal College of Science and Technology, Glasgow.

Lecturer/Senior Lecturer (with a degree in pharmacy or a related subject) in Pharmacy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 12).

Physicists (with a first- or second-class honours degree in physics and preferably a working knowledge of electronics and experience in one or more of the following fields: gas discharges, detonation processes or solid state physics), to undertake work in the field of electrical physics, devising novel items and proving their feasibility for special application—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. A/1640/34.

Scientists (degree standard), for research into the application of existing sources of energy and the exploitation of new ones in the iron and steel industry—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "F.T.5".

Senior Lecturer (with considerable practical experience in the rubber industry and professional and/or academic qualifications) in Rubber Technology; a Senior Lecturer (with laboratory and/or industrial experience of rubbers and rubber-like plastics and their physical testing) in Physical Chemistry of Polymers; a Lecturer (science graduate prepared to teach polymer chemistry and to work on colloid dispersions) in Polymer Chemistry; and a Lecturer (qualified young engineer prepared to treat rubber as an engineering material, particularly in dynamic applications) in Rubber in Engineering—The Clerk to the Governors, National College of Rubber Technology, Holloway, London, N.7.

DEW POINT APPARATUS

This instrument will interest any person or organization concerned in the measurement of the dew point or relative humidity of air in large or confined spaces.

The design ensures a rapid appearance and disappearance of the dew formation, while an insulated thermometer enables accurate temperature readings to be taken.

Synthesis of Phlorin and other Phenolic Glucosides by Plant Tissues.—A. Hutchinson, Chitra Roy and Prof. G. H. N. Towers . 841
Effects of Clipping and Spraying on Various Homœothermic Responses of Rabbits at an Elevated Environmental Temperature.—Dr. Harold D. Johnson, Chu Shan Cheng and A. C. Ragsdale 842
Validity of Motokawa's Technique for investigating Retinal Function.—Dr. C. I. Howarth and M. Treisman . . . 843
Passage of Phosphate through the Human Tooth.—P. Pincus . 844
Blocking Effect of Morphine on the Secretion of Thyroid-stimulating Hormone in Rats.—Milan Sámel . . . 845
An Abnormal Type of Lymphocyte.—Dr. B. Brausil . . . 846
Significance of the Adrenal Glands during the Post-natal Development of Thermoregulation in the Rat.—Dr. P. Hahn and O. Koldovsky . . . 847
'Gastric Para-Mucus'.—Dr. Franklin Hollander . . . 847
Distribution of Norepinephrine in the Heart.—Parkhurst A. Shore, Victor H. Cohn, jun., Benjamin Highman and Harriet M. Maling 848
Polymorphism in the β-Globulins of Sheep.—G. C. Ashton . 849
Giant Compound Hair Follicles in the Skin of the Rabbit.—Dr. H. J. Whiteley . . . 850
Capacitation of Mammalian Spermatozoa.—Dr. C. R. Austin and Dr. M. W. H. Bishop . . . 851
Effect of Gibberellic Acid on Fruit Set and Berry Enlargement in Seedless Grapes of *Vitis vinifera*.—Dr. Robert J. Weaver . 851
Effects of Kinetin on Cell Division in *Paramecium caudatum*.—Ruth Guttman and Avigdor Back . . . 852
Chromosomes and Chromocentres in the Nuclei of *Halidrys siliquosa* (L.) Lyngb.—Dr. Margaret Naylor . . . 853
Cytology of Indian Species of *Artemesia*.—Dr. T. N. Khoshoo and S. N. Sobti . . . 853
Chromosome Size in *Lolium temulentum* and *L. perenne*.—Beryl Naylor and Dr. H. Rees . . . 854
Fortifying Influences of Coconut Milk and Cow's Urine on 2,4-Dichlorophenoxyacetic Acid in the Control of Button Shedding in the Coconut.—S. R. Gangolly and Dr. K. M. Pandalai . . 855
An Infectious Fertility Factor for *Pseudomonas aeruginosa*.—Dr. B. W. Holloway and Pamela A. Jennings . . . 855
Acetylcholine in Milk.—V. P. Whittaker . . . 856
Use of Tidal Streams by Migrating Elvers (*Anguilla vulgaris* Turt.).—F. Creutzberg . . . 857
Relationship between Aggressiveness and Egg Production in the Domestic Hen.—G. McBride . . . 858
Sodium Phosphate Crystals on Salt Fish.—Dr. W. J. Dyer, Doris I. Fraser and J. R. Dingle . . . 858
Effect of Phenobarbitone on the Requirement of *Lactobacillus leichmannii* for Vitamin B_{12}.—Dr. G. H. Spray . . . 859
Resistance to Dieldrin in *Lucilla cuprina* Wied., the Australian Sheep Blowfly.—G. J. Shanahan . . . 860
Tryptophan Content of Wool.—D. R. Graham and K. W. Statham 861
Polymely in *Xenopus laevis*.—Dr. B. M. Hobson . . . 862
A New Type of Light Organ in the Deep-Sea Fish *Opisthoproctus*.—Dr. E. Bertelsen . . . 862
Effect on Earthworm and Diptera Populations of BHC Dust applied to Soil.—Jerzy J. Lipa . . . 863
Thermocline off the Coast of Tropical West Africa.—J. C. D. Watts 863
Bixbyite from Nagpur.—B. L. Sreenivas . . . 864

CHAPMAN & HALL

TRACE ANALYSIS

Edited by

John H. Yoe and **Henry J. Koch**

(*Professor of Chemistry and Director, John Lee Pratt Trace Analysis Laboratory, University of Virginia*)

(*Sloan-Kettering Institute for Cancer Research, New York, N.Y.*)

A JOHN WILEY BOOK

Size: 9¼ in. × 6 in. 685 *pages* *Illustrated* 96*s. net*

This book contains Papers presented at a Symposium on Trace Analysis held at the New York Academy of Medicine, and the first one to be devoted exclusively to the whole field of trace analysis. Each of the 24 contributors is a recognised leader in his respective field of analysis.

EMULSIONS

THEORY AND PRACTICE

by

Paul Becher

(*Central Research Laboratories, Atlas Powder Company, Wilmington, Del.*)

A REINHOLD BOOK

Size: 9¼ in. × 6¼ in. 392 *pages* *Illustrated* 100*s. net*

All modern developments in the theory and practice of emulsions are clearly explained in this new monograph. Much of the material is based on the developments of the last 15 years; but earlier work, when significant, is cited. The subject is so widely covered that it will bring those working in the cosmetic, food, petroleum, coating and textile fields thoroughly up-to-date.

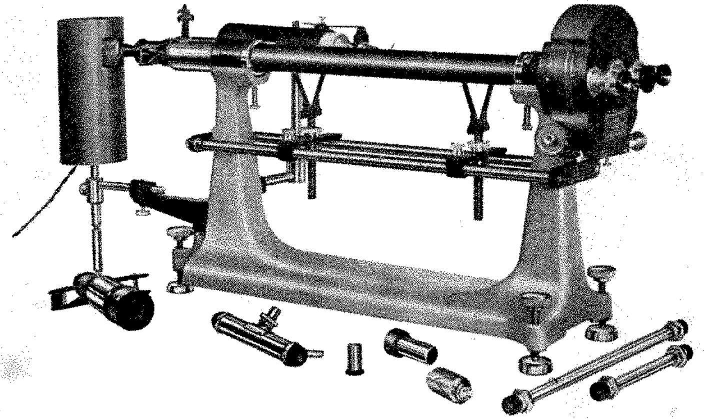
PRECISION INSTRUMENTS

Polarimeter Model A

This instrument gives the highest degree of accuracy with divided circle on glass reading to 0·01 degree



Circle centre on ball bearings.
Easily removable trough.
Divided drum replacing verniers.
Stationary observation telescope.
Circle reader enlarging image of scale.
Slow motion adjustment always in action.
Suitable, with additions, for measurement o
rotatory dispersion.

This polarimeter has been supplied in large number both in this country and abroad and has always bee acclaimed as being of advanced design and workmanship.

THE PRESENTATION OF SCIENCE

THE new policy recently announced by the Council of the British Association and discussed in *Nature* of January 4 represents in essence an attempt to improve the communications of science, particularly the understanding of science by the layman, and also the intercommunications of science itself. One aspect of this task is considered by Sir Lawrence Bragg elsewhere in this issue (p. 807). Sir Lawrence is Fullerian professor of chemistry in the Royal Institution, which was founded specifically for interpreting science to the public, although its early history shows that the word 'public' had to be interpreted in a narrower sense than is usual nowadays. However that may be, the Royal Institution has a worthy record in this field, won by the distinction of the professors who have been associated with it; and their distinction has been based on scientific achievement and also on the power to convey their knowledge to others. Both young and older people have been served in this way by the Royal Institution and, as Sir Lawrence comments, special efforts are now being made on behalf of the schools in the London area.

The distinctive feature of the Royal Institution lectures has always been the practical demonstrations, and indeed Sir Lawrence believes that this feature has been, and is of even greater significance than, the substance of the lectures. "The primary way to interest the general public in science is to show experiments and demonstrations and so let them share in the thrill of understanding how things work, which is, after all, a good popular definition of science." The Royal Institution has, of course, special facilities and the necessary technical staff to make such lectures possible, and Sir Lawrence estimates their cost at £5,000 a year. This is not a large sum in these days, and there is much to be said for establishing half a dozen or so such centres, properly equipped for lecture demonstrations, and distributed over Great Britain in accordance with density of population; no doubt some existing buildings could be adapted for the purpose. While this is a long-term scheme, the British Association has already shown how a move in that direction can be made without delay. Working in collaboration with some local education authorities in East Anglia and the Atomic Energy Authority, it arranged a talk on the peaceful uses of atomic energy accompanied by an exhibition of equipment in a school in Ipswich, and school children from the neighbourhood were enabled to attend. This is not the lecture demonstration that Sir Lawrence clearly has in mind, but it is a step forward. It suggests that other national bodies, nationalized industries and some of the larger industrial concerns should consider whether they cannot associate themselves with such a development. They have the technical staff and the equipment, and it should not be difficult, with the collaboration of education authorities and other local bodies, to arrange suitable public lectures.

Having said this much of Great Britain, it is of interest to learn what is thought in the United States about scientific communication—between scientists themselves, and between scientists and the general public.

The sixth annual report of the National Science Foundation had a section entitled "The Communication Report", describing the efforts of the Foundation to improve scientific information services in the United States, including both the information of the public and making federal research results more accessible. A Committee on the Social Aspects of Science, established by the Council of the American Association for the Advancement of Science in 1955, reported in December 1956 on the impact of science on American society likewise, and discussed difficulties in scientific communication and the public interest in science. The latest report of Dr. Caryl P. Haskins, president of the Carnegie Institution of Washington, discusses at some length the fundamental challenge to communication presented by the formidable diversities which characterize the scientific effort to-day.

Dr. Haskins points out that the interlocked character of the present world, the growing similarity of its cultures and the universality of its communication render meaningless any such designation as an Athenian or Elizabethan age; and he suggests instead that it can be characterized in terms of subject-matter, of the loci of ideas, and especially in the natural sciences, where, however, the present age confronts us with communications of almost new dimensions. Diversity of approach, he emphasizes, is the very life-blood of the scientific effort, and under the common rubric of scientists, not only do the observers differ widely in their characteristics, but also their subject-matter diverges even more. Scientific disciplines vary enormously among themselves in their degree of sophistication and in their intricacy; and although the new disciplines must always be in some measure rooted in the older, and the tested approaches of older fields generally have some relevance for the newer ones, the transfer is far from literal. It demands talent and sophistication in the investigator as well as the wisdom and sense of proportion derived from broad experience and a flexible point of view.

These profound diversities among investigators and within the structure of science, while characteristic and immeasurably precious, harbour also all the dangers of fragmentation, and pose the most serious challenges to communication within the core of the scientific effort. Many factors promote the compartmenting of subject-matter which constantly threatens the unity of science. The mere growth of vocabulary and specialization of terminology in a given field may render its jargon unintelligible even to an investigator working in an adjacent area. Even more formidable barriers to understanding may be presented by words, which are basically the coin of ideas and to some degree their generators, so that some basic concepts, as well as words, which govern scientists in one field of knowledge may be almost, if not quite, unintelligible to those in another.

Differences of language and concept, Dr. Haskins points out, tend to be reinforced by many of the social factors involved in scientific work. The scientist's desire to live and talk with those who will understand his meaning, and the pragmatic influences which lead him to seek identification with others in his immediate field, affect both the investigator and his work. While it means the exposure of each man's work to intimate and continuing criticism by his peers in the same general subject, it can harden an incipient conventionalism and raise the most serious barriers to communication within the body of science itself.

These challenges to communication within the framework of science, which have been taken up by the British Association with its new proposals for its annual meeting and for inter-meeting activities, are the background against which we should consider the further and, to some extent, intractable threat of fragmentation inherent in the very magnitude of the scientific effort itself and the consequent tremendous volume of scientific publication. This threat, as Dr. Haskins notes, has rapidly increased since the Carnegie Institution was established and, while some progress has been made in dealing with the sheer volume of paper, of titles and content, through the use of modern aids for storing and sorting information, intensive research could probably make them much more effective. The Nuffield Foundation is already doing something to encourage this, and a paper by Dr. H. Coblans in the *Unesco Bulletin for Libraries* last July elaborated proposals for new methods and techniques of communication. But the major need is, as was emphasized by Dr. R. E. Fairbairn in a paper read before the Society of Chemical Industry in March 1957, for new thinking about methods of providing information.

Such creative thinking, rather than the improvement and intensive application of mechanical aids, is the only way of meeting the basic challenge of communication inherent in the diversity of the natural sciences. Mechanical aids themselves will not stimulate the fruitful synthesis of ideas even in one field of work, or the transfer of systems of ideas from one field to another from which major innovations of point of view often arise, though their successful application can assist this process by removing obstacles. As Dr. Haskins wisely remarks, the vital factor, apart from the creative thinking already stressed, is a very particular type of environment such as is notably provided by the great universities and the great research institutes. From such environments, comprising communities of investigators, working together in a common mode but in divergent fields, in continuous converse, in sympathy and in rivalry, without predetermined goal, without over-commitment as a body to any given sector or to any one approach to the natural world, have come a goodly proportion of the real conceptual advances which have proved to be landmarks in the history of science.

The real value of the Science Centre in London, to which Sir Robert Robinson gave so much time and thought, during his tenure of the presidency of the Royal Society, lies largely in the contribution which it could render to that end, and it is from this point of view that the folly of successive Governments in rejecting the scheme should be judged. Dr. Haskins's arguments as to the importance of this kind of communication within the sciences at a time when the forces of fragmentation and diversity in science are more powerful and the barriers to interchange higher and more formidable might well stimulate a fresh attack on Government apathy and neglect. It is unlikely indeed that the scheme will be revived until we have in Britain not simply advisers with personal understanding of science, but men of science in posts comparable in standing with the appointment which President Eisenhower has recently made of Scientific Assistant, and also Ministers of State capable themselves of such appreciation.

Dr. Haskins points out that the creation of such an atmosphere is a task to which the Carnegie Institution of Washington is dedicated and for which it is unusually well equipped. As a scientific community, its membership represents almost the full range of gifts and attitudes already described, and its various departments address themselves to scientific fields ranging from the descriptive to the analytical, from the pioneer to the more sophisticated, while the mobility of its organization and its community of spirit preclude isolation either of workers or of fields. Moreover, since its whole work is directed to so-called uncommitted research, it is peculiarly fitted to assist this major task of scientific synthesis. Indeed, Dr. Haskins argues that in the future the Institution's task will be increasingly to lead the way to the breakdown of barriers between the numerous separate fields of knowledge and to the creation of new fields.

The methods used by the Institution, outside its internal substantive work, such as carefully planned and organized symposia and its relation to the universities, are, of course, widely used in Britain by the learned societies and professional institutions, and there are fellowship programmes comparable with the Vannevar Bush Fellowships of the Massachusetts Institute of Technology. As yet, at a time when the isolation of university departments is a matter of common criticism, Britain can, however, offer no such place as the Carnegie Institution in which such senior fellowships could be tenable. In the absence of such an institution, it should be a cardinal object of any strategy of research to provide the conditions which most favour scientific communication and the intermingling of disciplines, either by improvement in the mechanical means of communication or by the establishment of such opportunities as a Science Centre, for example, would provide.

Dr. Haskins, however, suggests that this is not the only challenge to communication to be met, and in the concluding part of his report he discusses the deeper unities that underlie the diversities of the scientific mode—the unities of value, of standard, of goal and of motivation. The kinds of communication which have had the most profound significance in human affairs have often been, he suggests, neither wholly conscious nor entirely verbal. They have come instead from the sharing of a common experience or a common view, simply and grandly symbolized, and can thus be largely divorced from material stimuli. Few bonds of communication can have been stronger, for example, or have had a deeper influence on the cohesiveness and the world view of a whole people, for good and for ill, than that Augustinian concept of knowledge and research which so dominated early Puritan America. Its exact opposite, however, the approach to Nature typified by the scientific revolution of the sixteenth and seventeenth centuries, has long since proved itself a mode of communication at least equal in its sweep, more flexible and perhaps more viable and, above all, conducive to positive action, and to the growth of ideas and to human joy. This effective entwining of philosophy with practical experiment is now some three centuries old, and Dr. Haskins argues that the very practical success of scientific research and the pragmatic genius of the American people make it imperative to see that these two strands do not become unwound. The inherently more basic element—science as a way of life—requires constant affirmation if it is to retain the vitality, allegiance and comprehension on which its vigour depends, and this is the prime task to which the Carnegie Institution is dedicated. Its most essential duty is to communicate, in virtue of its own mode of being, the essential verities of the scientific way that are too easily forgotten. On one side lie the joy and the underlying human values of the road of the investigator, the compelling life-challenge that is offered to the seeker after ideas about the natural world. On the other lie the great unities of approach and of preparation that bind those dedicated to the scientific path: the requirements of verification; the discipline of parsimony; the emphasis on individual effort.

As Dr. Haskins rightly comments, the scientific mode offers one means by which these priceless elements in human culture can be assured their proper and permanent place. Although it is in relation to the problem of communication that he has emphasized our need to defend and affirm these cultural elements, it might be as well to reflect that to do so may have other important consequences, especially for Britain. Exposition of the cultural values of science might well play a part in drawing into a scientific career a proportion larger than hitherto of the ablest and the most imaginative and constructive minds of the rising generation, upon whom the expansion of scientific and technological education depends; and this, in turn, must be the basis, not only of the material prosperity of Britain, but also of her position in the vanguard of scientific progress.

HUMAN ARTIFICIAL INSEMINATION

Artificial Insemination in the Human

By Dr. A. M. C. M. Schellen. Pp. xii+420. (Amsterdam: Elsevier Publishing Company; London: Cleaver-Hume Press, Ltd., 1957.) 72*s*.

THE practice of artificial insemination has, in recent years, become a commonplace. In cattle-breeding, it is now a well-established procedure, offering many advantages to the farmer. For him, fortunately, it appears to be devoid of controversy. When applied to human beings, as it appears to have been in some form or another since John Hunter, in the eighteenth century, is credited with having advised its successful use by a man with hypospadias, it has aroused strong emotions. Within the past twenty years, human artificial insemination has been used with increasing frequency, and public interest has steadily been growing. In general, insemination with the husband's semen (A.I.H.) has encountered little opposition except by the Roman Catholic Church, which, taking its stand on the fact that it is "contrary to Nature", prohibits it; and by those who will not countenance masturbation, the process by which alone semen can ordinarily be obtained in a form suitable for artificial insemination. Insemination with semen provided by a donor, be he anonymous or otherwise (A.I.D.), is obviously in a different category, since, in addition to any moral or religious problems it may raise, it is also fraught with a wide range of potential legal difficulties, about which the lawyers themselves find no unanimity of opinion. The subject, therefore, is one of far-reaching interest, and it is against such a background that Dr. Schellen's book must be judged.

Several things strike one on reading this book: it is a serious and scholarly attempt to survey the subject in all its minutiæ; it is exhaustive and very fully documented; it deals with many matters which are at most only barely relevant to the subject itself; it is unnecessarily repetitive—a source of irritation to the reader; it contains a great deal of sophistry, much the product of earlier writers to which reference is made, but much the author's own—another source of irritation to the reviewer; but perhaps most irritating of all is the bias which continually intrudes itself, especially against the practice of A.I.D. This would seem to have been introduced without the author's having actually been consciously aware of it, since the final chapter of the book is intended to represent the author's personal views, arrived at as a result of consideration of "all the facets of A.I." and its problems presented "as objectively as we could". The author is a Roman Catholic, and the attitude of his Church has very clearly coloured his emphasis on the numerous objections to A.I.D. and of the less-numerous ones to A.I.H., as well as his interpolations throughout the book. Whereas the literature records numerous highly successful instances of the use of human artificial insemination —not merely from the point of view of overcoming infertility but also from that of the happiness it has caused—Dr. Schellen dwells disproportionately on instances, almost entirely anecdotal, where the outcome has been psychologically or sociologically disastrous.

In spite of these criticisms, and because Dr. Schellen has made such a careful and extensive study of the subject, its literature and, by personal interview with some of its leading practitioners, its practice, his book is undoubtedly a very important contribution, providing an enormous amount of information on its legal, theological and sociological, as well as purely medical aspects. As such, it commands the attention of everyone whose interest in artificial insemination extends beyond the merely prurient or sensational.

G. I. M. SWYER

SCIENTIFIC PHOTOGRAPHY

Manuel de Photographie Scientifique

(Sciences Physiques et Biologiques.) Par Gérard de Vaucouleurs, Jean Dragesco et Pierre Selme, avec la collaboration de Henriette Faraggi et H. Tellez-Plasencia. Pp. 391. (Paris: Éditions de la *Revue d'Optique*, 1956.) 3,000 francs.

PHOTOGRAPHY has been usefully applied in almost every ramification of scientific work. It is probable that modern photographic techniques could with advantage replace many of the more laborious or less comprehensive methods, in use both in the laboratory and in the field, of obtaining and recording information. This manual makes available a large body of well-classified information (in the old-fashioned sense of the phrase) and is concise and lucid in its presentation. It should be of considerable value to those whose work involves photographic methods.

The earlier chapters are concerned with the properties of emulsions and descriptions of types of apparatus of use in various applications. A photographic darkroom is described and processing and after-treatment of the emulsion are discussed. Then follow sections dealing with special techniques for recording the various spectral bands, electron beams and charged particles. Geometric and photometric measurements are considered in some detail and the remainder of the text is devoted to discussion of several of the more important applications of the photographic method: photomicrography, cinémicrography, photomacrography, document copying, the photography of plants and animals and, finally, of landscapes in the broadest sense. A most useful appendix consists of forty-nine tables of quantitative information and there is a subject index to the whole.

There are some features which might perhaps receive the editors' consideration in another edition. The thirty-eight half-tone plates are not integrated with the text and are often far removed from the appropriate chapters. There is no general bibliography, each chapter having its own, and sometimes (for example, in Chapter 12) authors referred to in the text do not appear in the bibliography. The subject index could well be expanded considerably. Omissions include astrophotography (apart from two plates, of Mars and Finsler's comet respectively), aerial photography and photogrammetry and, more seriously because more generally applicable, stereoscopic photography.

One or two minor improvements suggest themselves: it is possible that estimation of exposures in colour photomicrography simply by measurement of the background (field) brightness might lead to under-exposure with less translucent specimens, and it is doubtful whether such treatment would justify the care in development of the film recommended on p. 202 (± 0·25 deg. C. and ± 10 sec. for first development). Reference might have been made to the ease with which most modern monochrome negative emulsions can be processed for reversal simply and satisfactorily. Perhaps a little more space could have been devoted to the question of depth of field in photomacrography and some mention made of the concept of 'circles of confusion' as an aid to calculation. Typographical errors are few. The page heading on p. 315 is obviously displaced from the following chapter.

This manual will be so useful in laboratories using photographic techniques that early consideration will have to be given to replacing the paper covers by a more substantial binding.

J. WALTON SIDDORN

YEASTS IN INDUSTRY

Yeasts

By K. Arima, W. J. Nickerson, M. Pyke, H. Schanderl, A. S. Schultz, A. C. Thaysen, and R. S. W. Thorne. Edited by W. Roman. (Biologia et Industria, 1.) Pp. 246. (The Hague: Dr. W. Junk, 1957.) 25 guilders.

THIS book is the first of a series of monographs to be called "Biologia et Industria" designed "to tell the industries using biological raw materials what the biological scientists and also the chemists and physicists can give them, and on the other hand to tell the scientists what industry expects of them". The main sections deal with baker's yeast, brewer's yeast, wine and fruit yeasts, sake yeasts, food and fodder yeast, and yeast preparations.

The articles are very uneven in content. They vary in style from Thorne's comprehensive and concise review of the literature on brewer's yeast with an average of 19 references to the page, to Thaysen's personal account of food yeast production with about one reference to the page. They vary in quality from the lucid and reasonably critical article on the cytology of yeast by Nickerson, in which only three minor errors were noted, to the article on wine and fruit yeasts by Schanderl in which some extraordinary statements are made without proof or reference, and in which errors are frequent. Overlapping occurs between sections as, for example, in the biochemistry of baker's yeast, brewer's yeast, sake yeast and food yeast, each of which is treated separately by a different author. At the same time there are gaps in the coverage so that some aspects of the subject, such as, on the scientific side, the taxonomy and ecology of yeasts and, on the technical side, the behaviour of yeast during distillery, cider and panary fermentations, are almost untouched by any of the authors. For the non-scientific reader the treatment is in general too detailed to appeal, and there are too many errors for the book to be recommended without reserve to the non-critical. For scientific readers the book is neither explicit nor stimulating in its treatment of what industry expects of them; for example, there is little discussion of where new knowledge might be of most value to industry or of where advances in technique are probable or desired. This book, therefore, cannot be said to succeed in the objects quoted at the commencement of this review, objects which are admittedly very difficult to attain.

Although scientific workers may find that in their own particular field the information given is insufficient to satisfy them, yet they should find that in other less familiar fields some of the articles are of interest and value to them. For example, the articles of Nickerson, Nickerson and Schultz, and Thorne are good and useful summaries of the literature up to about 1952 and in one short section to 1955; Pyke's articles summarize the literature up to about 1950 and give a fair idea of industrial practice; the article by Thaysen gives a very detailed description of the evolution and working of a plant for the production of *Torula utilis*; and Arima's short description of the preparation and composition of sake is probably the only one available in English. The book is adequately bound and printed, it contains eighteen figures and four plates, and carries on its dust-cover the reproduction of a very pleasant painting of sake barrels and bowl.

R. B. GILLILAND

MAGNESIUM IN PLANTS AND SOILS

Magnesium

The Fifth Major Plant Nutrient. By Dr. A. Jacob. Translated from the German by Dr. Norman Walker. Pp. xii+159+8 plates. (London: Staples Press, Ltd., 1958.) 40*s*. net.

THE importance of magnesium in crop nutrition has probably been under-estimated in many areas both by growers and to some extent by agronomists also. Dr. Jacob has undertaken through his book to rectify this failing by emphasizing the widespread significance of magnesium deficiency and correctly classifying magnesium as a major element in relation to the effects of nitrogen, phosphorus, potassium and calcium.

The first of twelve chapters deals with the chemistry of magnesium with reference to geochemistry, co-ordination and complex salt formation. The second and longest describes symptoms of magnesium deficiency in more than forty crops. Many descriptions are detailed and effective; some, however, for example, legumes and tomato, seem unduly brief and lacking in detail. Colour plates and black-and-white prints illustrate symptoms in several crops, but a number are either indistinctly reproduced or are not sufficiently close up to reveal diagnostic details. The association of 'sickle-leaf' in cocoa (p. 36) with magnesium rather than zinc deficiency without reference to other evidence may be questioned.

The discussion on ion antagonisms of magnesium is a useful contribution and it is gratifying to find an account of effects of nitrogen supply on magnesium requirements. Four chapters deal with magnesium content of plants and soils, selected methods of determining soil magnesium status, and the balance between plant uptake, soil content and fertilizer practice. In general these subjects are discussed in detail, informatively and widely. A chapter deals with results of fertilizer experiments with general crops including some tropical ones. The account of work on fruit trees and tomatoes is, however, brief and inadequate, though some further details are provided elsewhere in the final chapter on types of magnesium fertilizers.

Animal and human nutritionists will also find useful data in the chapter allocated to this field.

The functions of magnesium in plants are reviewed in Chapter 5, which provides much information on the effects of magnesium on their organic composition. In other respects, however, this important chapter is superficial in its treatment of biochemical aspects of magnesium function. References to specific phosphokinase and transferase enzymes are omitted. The glycolysis cycle and other major pathways of carbohydrate metabolism, many steps of which in plants depend upon magnesium-activated enzymes, are dismissed in some seven lines including but one reference of twenty years ago to 'saccharolytic cozymase', and a few references of doubtful relevance to unspecified phosphatase activity.

It is probably fair to suggest that Dr. Jacob intended his book to be read mainly by agronomists and soil chemists to whom these simplified ideas were addressed. It would be desirable, however, in a future edition to expand this treatment with a more detailed account of the biochemical role of magnesium in plants and in general, for the benefit of readers who do not normally study closely the literature in this field. The inclusion of an index would be helpful.

Soil advisory chemists, agronomists and all interested in mineral nutrition will nevertheless find this book useful and informative and will benefit from an appreciation of the widespread practical importance of providing the optimum magnesium status for soils and crops.

E. J. HEWITT

CALCIUM IN THE ANIMAL ECONOMY

Calcium Metabolism

By Prof. J. T. Irving. (Methuen's Monographs on Biochemical Subjects.) Pp. xi+177. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1957.) 11*s*. 6*d*. net.

ACCORDING to the final sentence of this book, "there is hardly any physiological action which does not involve the intervention of calcium". A reader unaware of this fact beforehand would certainly agree after reading Prof. Irving's monograph, where are to be found discussions on many different aspects of calcium metabolism. Confronted with so vast a field, the selection of topics for the space allowed must have been difficult. In the event, the choice will please many readers; especially those working on bones and teeth, for whom, in several ways, the author seems to have catered best. Cytologists, protozoologists and physiologists, on the other hand, and others interested in extra-skeletal calcium, may be a little disappointed.

The actual plan of the book seems logical. Dealing first with the calcium value of foods, the question of intestinal absorption is next considered; separate chapters discuss the role taken by phytic acid and vitamin D. There follows an account of the calcium content of the body and its various tissues. This might be made more complete by brief mention of the actual localization of the calcium in the tissues as revealed by methods such as microincineration. Subsequent chapters are concerned with the utilization and retention of calcium, and dietary requirements. There is an account of the calcium of the blood. Next follow three chapters on bone. The first of these deals with the histological features, the formation of bone, and the factors known to influence ossification. The usefulness of this chapter to the non-specialist reader would be much increased by the incorporation of a few simple diagrams. Next comes a description of the physics and chemistry of bone, followed by a discussion of the role of enzymes in ossification. At this point, the medical reader at least would have been interested to hear modern views on the causation and biochemistry of ectopic calcifications. Finally, there follow chapters on the calcium metabolism of teeth, the excretion and extra-skeletal functions of calcium. In future editions it might be possible to include a brief discussion of the part played by chelate compounds in its mobilization and transport. If, as has been suggested, certain of the cells of bone secrete chelating agents, our ideas about the part played by them will need revision.

This is a most useful review of the subject. The scope is wide, the style is clear and vigorous, and the work as a whole is illuminated by Prof. Irving's wide experience in the field. N. M. HANCOX

EPIDEMIOLOGY

Principles of Epidemiology

By Ian Taylor and John Knowelden. Pp. vii+300. (London: J. and A. Churchill, Ltd., 1957.) 30*s*. net.

Uses of Epidemiology

By J. N. Morris. Pp. viii+135. (Edinburgh and London: E. and S. Livingstone, Ltd., 1957.) 17*s*. 6*d*. net.

THIS is the first English text-book of epidemiology, and many first text-books tend to look rather solid and conservative soon after their production. They bring together the important investigations of the immediate past and attempt to confine them within general rules. This book is no exception. Epidemiology, being more a method of investigation than a separate discipline, appears to stand rather shakily on its own feet within these boundaries, and although one can understand its past successes, this book gives no clue as to its future development.

These criticisms, which could be directed at most text-books about an expanding but undefined subject, are not directed at the way this volume has been produced. It is a well-written account of the epidemiology of infectious disease with a large number of examples, and it includes a clear description of the statistical basis of the calculations leading up to the solutions. The assumptions made are those accepted by a graduate in medicine, and to a postgraduate student or to a teaching department this book could be the framework of an adequate and interesting course in epidemiology.

It is a fortunate coincidence that "Uses of Epidemiology" was published at about the same time as "Principles of Epidemiology". Although written for different reasons the two books are ideally complementary. Dr. Morris has felt free to speculate upon the wider applications of the epidemiological methods worked out by the classical school of investigators into infectious disease. The fields considered range from the evaluation of services to specific clinical problems. The flexibility demonstrated appears to be a function both of the possibilities which are present in the use of epidemiological techniques and the author's original outlook towards disease and treatment.

"Uses of Epidemiology" is a short book which can be read pleasantly in an evening. Many of the problems considered are under intensive study at the moment and it is probable that for this reason the book is easy to read now but will very quickly become dated. Some parts appear to be unnecessarily condensed and there is some difficulty in discovering the tables or figures referred to in the text. These disadvantages are minor ones and this series of ideas could be exciting reading to the epidemiologist or any medical graduate, and a gold mine to the postgraduate research worker looking for a subject or a cause. KENNETH NEWELL

VOLUMETRIC ANALYSIS

Volumetric Analysis

By Prof. I. M. Kolthoff and R. Belcher, with the co-operation of V. A. Stenger and G. Matsuyama. Vol. 3: Titration Methods: Oxidation-Reduction Reactions. Pp. ix+714. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 15 dollars.

AS Prof. Kolthoff says in his preface this third and last volume of "Volumetric Analysis" is long overdue. Volumes 1 and 2 of this series were published in 1942 and 1947, and are by Kolthoff and Stenger alone. Volume 3 is a much larger book than either of the preceding volumes and Prof. Kolthoff's account of the necessary changes of authorship reveals the magnitude of the effort needed for its completion.

It treats with commendable thoroughness and detail the practical aspect of one of the largest and most important sections of analytical chemistry. The reputation of the authors will be for most analysts a sufficient assurance of the worth of this book. Its detail is supplemented by a wealth of references, some of them as late as 1956. There are chapters on reactions, indicators and general techniques, permanganate, ceric salts, dichromate, iodometry, Karl Fischer reagent, iodate, periodate, hypohalites, ferrous and titanium salts and miscellaneous titrants. Electrical methods are not generally discussed, but an exception to this is made in dealing with the Karl Fischer method.

The treatment of each reagent includes sections on its preparation, stability and uses. Tests for purity of the reagents and of substances used in their standardization are given. It is interesting to notice that equivalent weights are given in the rational system of Schoorl as well as the international system. Methods of standardization are critically discussed. The collection of carefully selected methods for the determination of various inorganic and organic substances makes the bulk of the book. The scope of the work is evidently confined as in Volume 2 to these useful and reliable procedures, and as in that volume no attempt has been made to cover exhaustively all applications of the methods to specialized subjects in technical analysis. Many such applications are, however, given. Thus Lea's procedure for organic peroxides is included, but details of the bromometric titration of magnesium oxinate as applied to metallurgical analysis are said not to be within the province of the book. A detailed account is given of many applications of the Malaprade reaction.

This book is likely to remain for a considerable time the best and most complete account in the English language of this branch of analytical chemistry.

E. I. JOHNSON

Birds of Eastern and North-Eastern Africa

By C. W. Mackworth-Praed and Captain C. H. B. Grant. Second edition. (African Handbook of Birds, Series 1, Vol. 1.) Pp. xxv+806+53 plates. (London and New York: Longmans, Green and Co., Ltd., 1957.) 45*s.* net.

FOR those who do not know the first edition of this excellent book the following information may be given: the area covered comprises Sudan, Eritrea, Abyssinia, Somalilands, Kenya Colony, Uganda, Ruanda-Urundi, Tanganyika Territory, part of Nyasaland and part of Portuguese East Africa. 618 species, from ostriches to pittas, are described, species or subspecies being discussed under the following headings: distinguishing characters, general distribution, range in East Africa, habits, nests and eggs, recorded breeding, food, call, and distribution of other races of the species (if any). In the second edition six species and three subspecies have been added as well as a considerable number of notes on distribution, habits, breeding, etc. The small marginal maps showing the geographical distribution of each species described deserve special mention, being not only an excellent idea but also a great and important visual help for the reader. There are fifty-three tables in colour depicting 1,027 species, painted by Roland Green, H. Grönvold, D. M. Reid-Henry, Miss C. E. Talbot Kelly, and N. C. Lighton, and six tables of excellent photographs by Van Someren.

It is a pity that a bibliography has not been included in the book. A work of this kind (even in spite of the authors' intention) is considered by most readers as a reference book, and for this reason its value would be enhanced if it were to contain references to the most important sources of information. A full bibliography of the East African birds is badly needed and the authors are certainly the ornithologists most competent to compile such a work, which might usefully form a third, supplementary volume to this book.

Elsevier's Dictionary of Electronics and Waveguides in Six Languages

English/American, French, Spanish, Italian, Dutch and German. Compiled and arranged on an English Alphabetical base by W. E. Clason. Pp. viii+628. (Amsterdam: Elsevier Publishing Company; London: Cleaver-Hume Press, Ltd., 1957.) 90*s.*

THIS volume is one of an excellent series in which technical terms are defined in English, and then the corresponding words or phrases are given in five other languages. An ingenious arrangement of numbering the terms, which are in alphabetical order, makes it very easy by a simple cross-index to translate a term from any of the other languages. An earlier volume dealt with the terms used in the fields of television, radar and their associated antennæ (see *Nature*, 177, 1099; 1956); the present book covers the corresponding subjects of electronics and waveguides. More than 2,000 terms are defined and they include most of, if not all, the accepted words and phrases used in semiconductor and transistor work, as well as in the general field of electronics. Terms relating to physical electronics are not, however, included since it is intended to deal with the subjects of nuclear science and technology and radiation in a subsequent volume. It is noteworthy that the present dictionary includes definitions already established by the British Standards Institution, the International Electrotechnical Commission and the publishers of the "International Dictionary of Physics and Electronics". As with the former volume referred to above, the book is very well produced in a handy size, with a flexible binding and a convenient thumb-index to the different languages. These qualities combined with the high technical standard throughout make this dictionary a reference work of permanent value to scientists and engineers engaged in the use of electronic devices and microwave equipment.

R. L. SMITH-ROSE

Lecture Notes on the Use of the Microscope

By R. Barer. Second edition. Pp. vii+76. (Oxford: Blackwell Scientific Publications, 1956.) 7*s.* 6*d.* net.

DURING the three years since its first appearance, Dr. R. Barer's little book has become known to a wide circle of scientists; it is evident from the demand for a second edition that this book meets a definite need, by introducing biologists to the correct use of one of their most important tools. As a result of the increasing use of the electron microscope in biology, it might be thought that the usefulness of the light microscope would diminish, but it is evident that the two methods should be used in conjunction, and that the proper use of the light microscope will continue to be of extreme importance. Dr. Barer has deliberately omitted any mention of the specialized forms of modern microscopy, because, as he points out in his preface, these methods are still in a state of flux but the fundamentals of direct microscopy do not change.

There have been only minor alterations in this edition, which resembles the earlier one in retaining its valuable chapters on the theory of the microscope and practical instructions for its use. The appendixes are of particular interest, giving simple experiments to illustrate such points as the effect of numerical aperture of both the condenser and the objective on resolution; the use of Köhler illumination is also described in detail. The book is very well written, and provides a clear explanation of the basic theory of the microscope; although it is intended for biology and medical students, all users of the microscope would be well advised to study it. If they did so, there would perhaps no longer be grounds for the author's opening comment that, "Probably no instrument is more often misused than the microscope".

S. BRADBURY

Old Stone Age

By Stevan Celebonovic, with a Commentary by Geoffrey Grigson. (Nature and Art: a Series.) Pp. 96. (London: Phoenix House, Ltd., 1957.) 30*s.* net.

AS a picture book this volume is delightful and has a real value for the prehistorian. While many of the plates illustrate well-known palæolithic works of art, a number represent sculptures and drawings that are less known and not often reproduced. Frankly, the text is not very helpful, though some readers will find the chronological table at the end useful. Specialists will find little they did not know already, and non-specialists will not learn very much about the art or the cultures that produced it. But, of course, the illustrations are what really matter and at the price they are truly magnificent. No prehistorian should fail to have a copy by him, and the ordinary reader interested in art photography will revel in the beauty of some of the cave and home art subjects as here presented.

M. C. BURKITT

POSSIBLE CORRELATIONS BETWEEN EARTHQUAKES AND MICROSEISMS

By C. A. NANNEY
Department of Physics, University of Chicago

IN August 1954 I observed that a rapid decrease of microseism frequency (inverse period) occurred in coincidence with the Samoa Islands earthquake ($M = 7$–$7\frac{1}{4}$) which occurred at 4h. 42m. G.M.T. on August 18, 1954. The observation was made at the Naval Research Laboratory's Microseism Station at Chesapeake Beach, Maryland. Afterwards, an investigation was undertaken to determine whether the observed change of the microseism frequency might have been correlated with the earthquake, or might have arisen as a chance coincidence, since the microseism frequency is known to vary in time.

To the best of my knowledge, no studies have been carried out to determine whether any correlations exist between earthquakes and microseisms. The following discussion is a summary of some interesting and apparently significant results of such a study.

Microseismic data covering a span of three years were analysed. Most of them (about 90 per cent) were from previously published papers, and the rest were taken by me. The three-year total is the sum of various intervals of data from some eight stations the distribution of which virtually encircles the globe.

Since earthquakes occur fairly frequently, an unbiased sampling method must be used in their selection for a study of this kind. The sampling criteria for earthquakes (such as, all earthquakes occurring during the interval covered by data with magnitude greater than $6\frac{1}{2}$, or all earthquakes with depths reported greater than 30 km.) were established prior to the study of a given set of data. In the subsequent analysis, all earthquakes which fell in the specified category were used, and none was omitted. Similarly, the whole interval of data which were available was always used, and no sets of data analysed were omitted from the statistical tests. The earthquake occurrence times and other relevant information were taken from well-documented sources, such as the "International Seismological Summary". Altogether, some three hundred earthquakes were considered in the analysis.

It should be pointed out that the problem was considered almost entirely on the basis of earthquake information, and no attempt was made to interpret existing meteorological and oceanographical conditions. These conditions are not as well defined as earthquake data (for example, time of occurrence, location, etc.). Furthermore, it is entirely possible that several of the numerous postulated mechanisms for the generation of microseisms may exist at any one time.

Nevertheless, in a statistical study of this type, it is possible to consider the earthquakes independently of any other phenomena which might alter the microseisms. First, if there is no correlation between microseisms and earthquakes, the number of cases contradicting, and the number of cases supporting, the correlation will tend to average out in a statistically large sample of data, and the correlation will not be supported at any statistically significant level. Secondly, any changes of microseisms due to other phenomena will only reduce any correlation that might exist between microseisms and earthquakes, thus requiring a large quantity of data to establish a correlation between the latter, if one should exist.

The findings to be discussed are all based on results which were found to be significant at the 0·01 significance-level. Most of them were significant at a considerably higher level.

The study disclosed that the microseism frequency begins to increase approximately 24 hr. before the occurrence of many large earthquakes. The increase of frequency continued to approximately the occurrence time of the earthquake, and the frequency decreased following the occurrence of the earthquake. The amplitude of the microseisms was found to increase before earthquakes and to decrease afterwards in a similar manner. The average changes, for earthquakes with magnitude $6\frac{1}{2}$ (Gutenberg–Richter scale) or greater, appear to be approximately a 10 per cent increase of the frequency and a 20 per cent increase of the amplitude. The maximum changes that have been observed, which were believed to be associated with seismic phenomena, were an 80 per cent increase of the frequency, and a number of cases of several hundred per cent for the amplitude increase. However, there were some large earthquakes for which no increases of frequency or amplitude were evident.

Microseism data from the following stations were studied: Japan, Guam, Hawaii, California, Missouri, Maryland, New York and Finland. The results indicated that a correlation between earthquakes and microseisms existed at all these stations. The frequency and amplitude effects have been observed for earthquakes which occur at very great distances, even a semi-circumference, from the microseism station. A simultaneous change of these parameters has also been observed to occur for widely separated stations in coincidence with a particular earthquake.

In general, the frequency and amplitude increases occurred only for the larger earthquakes ($M \geq 6\frac{1}{2}$); however, two exceptions were found. First, smaller earthquakes, if closer to the microseism station, were often found to be associated with significant increases in the amplitude and frequency of the microseisms. Secondly, deep earthquakes, though not necessarily large, were found to be correlated with increases of the microseism amplitudes.

The data analysed showed that there is reason for believing that many of the so-called 'microseism storms' may be correlated with earthquakes. This conclusion is based upon a study of a number of papers on microseism storms. From these, the following example is given for illustrative purposes.

Rameriz[1] graphs the microseism amplitudes at St. Louis for about six months of 1938. A study of the microseism storms and earthquakes occurring during this interval disclosed that the time of the maximum intensity of a majority of these storms coincided closely with deep or large earthquakes. The possibility that the correlation observed might be due to chance was shown to be less than one in ten thousand.

Infrequently occurring, long-period (greater than ten seconds) microseisms are known to exist. A study of microseisms of this type was conducted by Oliver and Ewing[2] during the Atlantic Ocean hurricane seasons of 1954–55. The amplitude of these microseisms often reached a maximum, and rapidly decreased during a time when any existing hurricane, its path and its distance from the microseism station exhibited no unusual change. An examination of earthquake records revealed that a majority of the long-period, microseism-amplitude maxima occurred in close coincidence with either a deep earthquake or a relatively local quake occurring in the Atlantic Ocean. The correlation between a maximum of the amplitudes of the long-period microseisms and the occurrence of one of these two types of earthquakes was very strong and far greater than would be expected by chance. Since the authors[2] point out that a hurricane is not a necessary condition for the occurrence of this type of microseism, there is reason to believe that some of these long-period microseisms may be related to earthquakes, particularly deep ones. Indeed, this is not an entirely new suggestion, as I discovered later. Donn[3], in noting similarities between these and certain types of earthquake waves, has suggested that there might be a relationship between the two.

Numerous attempts have been made to locate meteorological storm centres by means of microseism propagation directions. In many cases these were not completely successful, and were largely abandoned as a consistent means of locating storms. I studied several papers[1,3] where microseism directions were given for times during which no hurricanes were present. This study revealed that the directions found for the propagation of the microseisms sometimes showed rather remarkable agreement with the azimuth directions of the great circle path from the microseisms station to the location of impending earthquakes of significance.

For example, Rameriz[1] determined the azimuth of propagation of microseisms at St. Louis at frequent intervals during the month of November 1938. The majority of these fell in the octant between N. and N.N.E. However, of the six exceptions to this octant, four were found to correspond in time to the intervals during which four significant earthquakes occurred. Two of the earthquakes were probably the largest during the interval for which data were given, the third was relatively close to the station, and the fourth was of deep focus.

However, even more remarkable than this coincidence in time were the results of a comparison made between the four observed microseism directions and the azimuths to the respective earthquakes. The first three cases agreed within three degrees and the fourth case differed by fifteen degrees.

While the directional correlation was greater than expected by chance, I do not believe that the data examined to date are sufficient to constitute a conclusive case for a directional correlation with earthquakes. It is merely pointed out here as being a possibility which has some substantiation, and should be further considered.

The preceding observations offer some hope that they might lend themselves to the prediction of earthquakes. Whether any predictions can be made by utilizing the preceding effects awaits detailed investigations of the earthquake-microseism problem and its ramifications. I hope this article will cause sufficient interest to result perhaps in the genesis of some such investigations.

Even if such an endeavour does not prove successful, the studies should give new insights into the Earth's crust and interior, as well as a better understanding of the little-understood microseisms.

I would like to thank Profs. Harold C. Urey, John C. Jamieson and A. W. Lawson, of the University of Chicago, for the opportunity to discuss this problem with them. I am particularly grateful to Dr. J. E. Dinger, at the United States Naval Research Laboratory, for his continued support and advice.

A detailed report of the study is to be published in the near future.

CONTROLLED THERMONUCLEAR REACTIONS

A DISCUSSION on thermonuclear reactions was held by the Royal Society on February 5. The chair was taken by Sir Cyril Hinshelwood, and the discussion was opened by Sir John Cockcroft, director of the Atomic Energy Research Establishment.

Sir John briefly outlined the earlier work which has led to the present successes in the thermonuclear field. He spoke of the discovery of the D–D reaction by Oliphant, Harteck and Rutherford in 1934, of the pinch effect by Northrup in 1907, and of its experimental consequences by Tonks in 1939. Of the more recent work, Sir John emphasized that of Ware in 1948 on toroidal discharges, of Kurchatov on straight pinches, and of Bickerton and Tayler in England, Rosenbluth in the United States and Shafranov in the U.S.S.R. on the use of an axial stabilizing field. Bickerton and Tayler had established that metal walls and axial fields could together definitely stabilize a discharge. After mentioning the work of the laboratories of Associated Electrical Industries, Ltd., and of the Los Alamos group, Sir John briefly described the papers to be presented. He concluded by pointing out that much useful work could be done in the universities in the now unfashionable field of atomic physics on such processes as excitation and ionization in stripped atoms.

Dr. P. C. Thonemann, who read a paper entitled "The Plasma Physics of ZETA", said that ZETA is essentially a large transformer with which high currents are passed through a low-pressure gas. The ring current in the gas forms the secondary of the transformer. A ring current of this type is self-constricting, but highly unstable: to achieve stability an axial magnetic field is used in conjunction with a metal-wall vacuum vessel. The most significant aspect of the results obtained with ZETA is that stability can be achieved in a toroidal tube.

An isolated plasma is a diamagnetic body, which can remain in an equilibrium position indefinitely in a static magnetic field. As a result of collisions, however, the currents giving rise to plasma diamagnetism decay with time, until finally the gas is no longer confined. The time for which isolation of the gas from the walls can be maintained increases with the electrical conductivity of the gas, which in turn increases rapidly with temperature. On the other hand, high temperatures cannot be produced until isolation from the walls is achieved. Thus the required conditions of isolation and high temperatures cannot be approached stage by stage.

As a result of experiments by R. Carruthers and R. J. Bickerton, ZETA was designed to achieve stability by using metal walls to remove long wave-length instabilities, and axial magnetic fields to remove short wave-length instabilities.

The best indications that the discharge is, in fact, stable are obtained from measurements of the internal magnetic field. Provided the gas can be prevented from breaking up into small pieces, the possible containment-time increases as the square of the linear dimensions of the system. The large size of ZETA has been justified by the containment-times achieved; at present these are only limited by the energy available from the external circuit.

The stable configuration is set up in the following way. Deuterium at a pressure of about 10^{-4} mm. of mercury is weakly ionized by a radio-frequency oscillator. An initial electric field of about one volt per centimetre is applied to the surface of the gas, the ratio of electric field to pressure being chosen to give the maximum rate of ionization without causing the electrons to behave as though they were in an accelerator. As the electron-density increases, current flows predominantly at the discharge surface. When the field due to this current exceeds the axial field initially present, the discharge contracts, and provided the contraction is fast enough the axial flux inside the discharge is conserved. If the metal wall is sufficiently thick no further flux can penetrate it, and the field between the discharge and the walls is just that due to the axial current. Such a system, with sharply separated fields, is known to be stable for short wave-length instabilities. In ZETA, conditions lie between the extremes of completely separated fields and uniformly mixed fields. The time for which such a system remains stable is not yet known.

The metal walls, in addition to excluding the axial magnetic field after the collapse of the discharge, serve to stabilize the discharge against long wave-length instabilities. This is achieved by the image current induced in the wall by any movement of the ring current. The required stability cannot be obtained unless the conductivity of the gas is sufficiently high. This implies almost complete ionization and electron temperatures in excess of 10^5 °K. in the early stage of the discharge, before collapse.

Dr. Thonemann said that the discharge is cooled largely by radiation from impurities, and not by particle bombardment of the walls. Thus, when a probe of area 1/3000th of the wall area is immersed in the discharge, the neutron flux is reduced to an almost undetectable level and the resistance of the discharge is greatly increased. The high temperatures, thermonuclear reactions, and all the other interesting observations follow as a natural consequence once stability has been achieved for relatively long times. If the gas column remains stable as the magnetic fields confining it are increased, then there are no fundamental reasons why temperatures exceeding 10^8 degrees should not be produced.

A paper on "Experiments with ZETA" was read by Mr. R. S. Pease, who said that ZETA is essentially an apparatus for producing high temperatures. The first task, when ZETA began to work on August 12, 1957, was to find the best operating conditions. The guiding principle was that the highest temperatures were likely to be obtained with the largest currents, the lowest starting pressures, and the lowest axial magnetic fields compatible with a discharge which did not damage the apparatus. After considerable experimenting it was found that the best values for the axial field and initial pressure are 160 gauss and $\frac{1}{8}\,\mu$ of mercury (in deuterium). During this experimental period it was noted that alarming voltage transients of up to 1 kilovolt appeared between adjacent liners; this led to concern about the glass-tape insulation between the liners. Another phenomenon encountered at this stage was the sudden fall in current at the end of the pulse, associated with a formidable voltage transient. It is now known that the transient appears when the torus is clean, but a satisfactory explanation of it is not yet available.

Neutrons were first observed on August 30 when the current reached 120 k.amp. at an axial field of 160 gauss and a pressure of $\frac{1}{8}\,\mu$ of mercury. The results of other investigations carried out on ZETA at that time have already been reported in *Nature* (January 25, p. 217).

Mr. Pease described some of the work undertaken since October. The machine has been improved in a number of ways: the insulation between the liners has been changed to polytetrafluoroethylene; irregularities have been removed from the axial magnetic field; the current pulse has been prolonged and condenser overswing prevented by short-circuiting the discharge when the condenser voltage drops to zero. Further modifications to obtain high currents are possible, but these involve removing protecting devices from the circuit and have not yet been attempted. It is hoped soon to replace the liner system by an improved one.

Mr. Pease concluded by describing the magnetic probe measurements; they confirm the densities and temperature obtained by other methods, and show that the gas is confined. They also show, however, that there is considerable mixing of the magnetic fields, and that the volts per turn at maximum current is not that associated with the resistance of the main channel.

When the discussion was resumed, with Sir John Cockcroft in the chair, Sir George Thomson complimented Sir John and the Harwell team on their achievement. He said the evidence that the observed neutrons have a true thermonuclear origin is strong. The temperature measurements themselves are sufficient to indicate that neutrons should be produced. If the neutrons are not thermonuclear, then the temperature measurements are in error and there must be a non-thermal neutron source which, by chance, gives the neutron yield predicted for the incorrect temperatures; Sir George himself did not believe this.

Sir George went on to indicate the importance of electric fields in contained plasmas. The ions in ZETA have a large Larmor radius and would reach the walls in a very short time by scattering. The electrons, however, have a small Larmor radius and are firmly contained. The strong electrostatic correlation between the electrons and ions prevents the ions reaching the walls. The particle paths, being influenced by these strong electric fields, are trochoidal. These electric fields will get stronger and stronger as temperatures get higher.

Dr. A. A. Ware, of the Associated Electrical Industries Research Laboratory, gave an account of the work done there with a torus, Sceptre III, the dimensions of which are scaled down by about one-third compared to ZETA. The design of Sceptre III was originally based on theoretical proposals made by Liley at the beginning of 1957, but in view of the results obtained with ZETA a larger torus than that proposed by Liley was used. The main constructional difference between ZETA and Sceptre III is that the latter has the primary turns near to the torus. This construction reduces the leakage inductance and increases the gas current.

Much information has been obtained from inductance and resistance measurements made on the current and voltage wave-forms. In particular, the skin depth before the discharge leaves the wall is about 1/20th of the tube radius at high magnetic fields, and somewhat larger at lower magnetic fields. Measurements of inductance at peak current indicate that 90–100 per cent of the applied axial field is trapped by the contracting discharge.

Temperatures obtained from the neutron yield agree well with those from spectroscopic measurements. The variation of neutron yield with axial magnetic field shows a peak at that magnetic field which corresponds to the discharge being compressed to one-third of the tube diameter at maximum current. This is to be expected, since the heating of the gas increases with compression, but the discharge becomes unstable if it is compressed too far. Unlike the results obtained with ZETA and Perhapsatron, a maximum with respect to pressure has been found in the neutron yield. Neutrons appear shortly after the discharge has left the wall and the yield rises to a maximum around peak current. Neutrons continue to be emitted into the second half-cycle of the discharge.

Dr. Ware then referred to the comparison of the results with the theoretical predictions of Liley. Results obtained recently have tended to spoil the good agreement reported earlier[1]. The main discrepancies are: the skin-depth is small, a higher temperature is predicted than is observed, there are indications that the electron temperature is less than the ion temperature, and the temperature, as calculated from the neutron yield, does not vary in the right way through the pulse.

Dr. K. W. Allen (Atomic Weapons Research Establishment, Aldermaston) gave an account of work at Aldermaston on straight-tube discharges of short duration, the object of which is to heat the ions directly rather than by way of the electrons. A collapsing current sheath is set up which accelerates radially, the electrons by the pinch effect, and the ions by the electrostatic action between them and the electrons. In this way ions and electrons acquire equal velocities so that the ions get virtually all the energy. Rapid heating requires large sheath velocities and hence minimum circuit inductance. This has been achieved by using an arrangement of parallel spark gaps to discharge the condenser bank so that the inductance is that of a single unit divided by the number of units. A circuit has been devised such that all the gaps can be fired in less than 10^{-8} sec.

Neutrons were first observed at the rate of 10^4–10^5 per pulse on Christmas Eve, 1956. Typical conditions are: bank voltage 9 kV. and pressure 30 μ of mercury in a silica discharge tube 28 cm. long and 15 cm. in diameter. The initial rate of rise of current is 5×10 amp./sec., which is three times faster than that reported by Artsimovich and half that obtained at Los Alamos. Other workers in the field have reported that the neutron yields are very sensitive to impurities and magnetic fields, but this has not been confirmed at Aldermaston, where the yield has been found to be reduced only by an order of magnitude by 5 per cent of nitrogen or by 1,000 gauss axial magnetic field. Artsimovich reported that a few hundredths of a per cent of oxygen, argon or xenon quenched his yield, and Colgate reported that an axial field of 100 gauss reduced his neutron yield by four orders of magnitude. These results suggest that the mechanism responsible for the neutron production in the Atomic Weapons Research Establishment apparatus is different from that proposed by Colgate.

Dr. Allen concluded by saying that a larger condenser bank is under construction. It is hoped that this bank will give rise to a larger neutron yield which will permit a more detailed investigation of the mechanism of neutron emission.

Dr. J. D. Jukes, of Harwell, presented some comments of Dr. R. J. Bickerton and Dr. H. London (Atomic Energy Research Establishment, Harwell) on the scaling laws for stabilized discharges. Dr. Jukes said that, since various groups are seeking to produce thermonuclear temperatures in stabilized pinched discharges, it is desirable to compare similar experiments and to attempt to forecast the requirements of an economical reactor working on this principle by the use of scaling laws.

It can be shown that if I, the total current, and N, the line density, are kept constant, then the characteristic times of the various physical processes which determine the growth and life-time of the pinch, such as ohmic heating, relaxation, field diffusion and radiation cooling[2], are all proportional to R^2, where R is the tube radius. Furthermore, the temperatures are the same at corresponding phases of the life-time of the discharge.

The stable life-time is proportional to R^3, while the neutron yield Y during this time is proportional only to the axial length, and the fraction of nuclear burn-up is independent of size. The radiation flux to the walls per pulse is proportional to R^{-1} and the rate of rise of current required to trap the magnetic field is proportional to R^{-2}. This indicates that there is some engineering advantage in using a large apparatus.

Table 1 compares results of three experiments in the light of these scaling laws. The quantity nt, where n is the density and t the containment-time, is a measure of the efficiency of a reactor, as pointed out by Lawson[3]. This quantity must be increased to 10^{14} at least, and T to 4×10^7 °K. to make a device operating on the deuterium–tritium mixture produce net power. Extrapolating from ZETA this would require a current equal to or greater than 10^6 amp.

Table 1

	ZETA	Sceptre	Perhapsatron $S3$
I (k.amp.)	180	160	200
R (cm.)	50	15	2×5
N (cm.$^{-1}$)	6×10^{16}	8×10^{16}	6×10^{16}
t (sec.)	10^{-3}	10^{-4}	6×10^{-6}
L (cm.)	10^{3}	360	200
Y (neutrons)	10^{6}	10^{5}	2×10^{5}
tR^{-2}	4×10^{-7}	5×10^{-7}	8×10^{-7}
YL^{-1}	10^{3}	3×10^{2}	2×10^{3}
nt	10^{11}	10^{11}	10^{11}

Dr. W. B. Thompson (Atomic Energy Research Establishment, Harwell) gave a theoretical analysis of the operation of ZETA on the assumption that it produces a stable configuration very like that described by Dr. R. J. Tayler[4] later in the discussion, and that most of the heating is Joule heating. The process can be described as occurring in three phases. In phase 1 (0 to 100 μsec.) the gas is ionized, heated and a current skin formed, separating the axial and azimuthal fields; in phase 2 (100 μsec. to 1·5 msec.) the gas is compressed; and in phase 3 (1·5 msec. to end of pulse) the current skin slowly widens, the axial and azimuthal fields interpenetrate and eventually the plasma loses its stability.

Dr. Thompson showed that at the end of phase 1 the current sheath is 5 cm. thick, the temperature is 1·5–2·0 × 10^5 °K., and there is approximate thermal equilibrium. In phase 2 three processes are important: adiabatic compression takes the temperature to about 10^6 °K., Joule heating adds about another 2 × 10^6 °K., and finally shock heating may add a further 5 × 10^5 °K. Thus, at the end of phase 2 the temperature is 3–3·5 × 10^6 °K. During phase 3 there is little further heating and the discharge loses stability. On the basis of Dr. Tayler's calculations (described later in the discussion) the discharge life is 1–2 msec.

Dr. Thompson concluded by saying that the picture he described is not in disagreement with the observations made on ZETA, with the exception of the magnetic-probe measurements. Magnetic probes, however, considerably disturb the discharge and thus may not give a good picture of what happens in their absence.

If the probe results are meaningful and applicable, then some other theoretical model will be needed. An example would be a turbulent but confined plasma, which would make well-mixed fields and high temperatures quite intelligible, but there is little experimental evidence for such a system.

Dr. R. J. Tayler (Atomic Energy Research Establishment, Harwell) spoke of the stability of mixed-field systems. He said that earlier work has shown that there should exist stable configurations of a pinched gas discharge if the currents flow entirely on the plasma surface. Dissipative processes will result in an interpenetration of magnetic fields. An estimate has now been made of the amount of penetration that can occur before stability is lost. A variational method developed at Princeton has been used, and with simplified profiles for the mixed fields, calculations have been made with a succession of trial functions. Results obtained for trial functions with between one and four arbitrary parameters show a change of only 5 per cent in the amount of penetration that can occur. For one initial configuration for which results have been obtained, the field can penetrate through about 15 per cent of the discharge radius. As there is no initial axial magnetic field outside the discharge in this configuration, the estimated duration of stability obtained from it is likely to be optimistic.

These results suggest that a stabilized pinch in ZETA can have a life-time measured in milliseconds. However, it is not clear from the measured magnetic field profiles that a stabilized pinch of this type actually occurs in ZETA.

Dr. Tayler concluded by giving an account of the article on "Co-operative Phenomena in Hot Plasmas" by Prof. L. Spitzer that appeared in *Nature* of January 25, p. 221.

Dr. D. Gabor (Imperial College of Science and Technology) thought that the discrepancy pointed out by Prof. Spitzer is real, and that co-operative processes may well be responsible for the high ion temperatures observed in ZETA and in Sceptre III. It seems necessary to postulate two collective mechanisms: one for transferring energy in a locally ordered form from the electrons to the ions, and one for creating molecular disorder in the ion gas. It is easier to make a guess at the second mechanism, because this may well be essentially similar to that responsible for 'Langmuir's paradox' in low-pressure arcs[5]. In these arcs electrons exchange energy with one another very rapidly, not through collisions but through the intermediary of an oscillating boundary layer. This has a potential distribution and an oscillation frequency such that electrons diving into it and returning to the plasma emerge with a resultant gain, at the expense of those electrons which have dived into the sheath an odd number of half-cycles earlier and have delivered energy to the oscillations. There exists a similar boundary sheath in the pinched discharge, with the difference that—due to the magnetic field—the ions are outside. It is very likely that this sheath is the seat of oscillations with a frequency of about twice the gyromagnetic frequency of the ions, thus creating intense interchange of energy between the ions and an energy distribution which is very nearly Maxwellian.

It is more difficult to guess at co-operative phenomena which may transfer energy from the electron gas to the ions. In the ordinary arc there is no such exchange, as the plasma-frequencies of ions and electrons are widely separated, by a factor of about 60 in the case of deuterons. On the other hand, the Larmor frequency of the electrons in ZETA is of the same order (10^9 cycles/sec.) as the ion-plasma frequency, so that a necessary (but by no means sufficient) condition of co-operative interaction by oscillations appears to be met. Dr. Gabor conjectured that even under conditions when the plasma boundary as a whole is stable, there may be growing helical waves in the electron gas, essentially at right angles to the magnetic field, and weakly coupled to the ion–plasma waves, which are approximately parallel to it. Weak coupling makes the energy pendulate between the two types of waves, but during the periods when the energy is in the ion gas this is converted into disordered, thermal motion by the first-mentioned mechanism, thus preventing its return to the electron gas. To check these hypotheses it may be of interest to look out for strong oscillations in the 1,000-megacycle range.

INTERPRETATION OF SCIENCE TO THE PUBLIC

By Sir LAWRENCE BRAGG, O.B.E., F.R.S.
Royal Institution, London

SIR ALEXANDER FLECK'S recent address to the general assembly of the British Association, and the editorial in *Nature* of January 4, will be warmly welcomed by all who are interested in the popularization of science. The new plans for enlarging its activities which the British Association has announced focus attention on the need for presenting science in the most effective way to the general public. I am writing about this subject because the experience and traditions of the Royal Institution may afford some useful pointers in our endeavour to interest the public in science. It was founded 160 years ago for the special purpose of interpreting science to the public, and apart from the prosecution of research in its laboratories this has continued to be its primary function. The art of popular lecturing might indeed be said to be its main subject of research.

One of the oldest and most honoured traditions is that a 'Discourse' should be profusely illustrated by experiments and demonstrations. A popular talk to laymen differs in many ways from a lecture to students or an address to a learned society. To a professional scientist the description of an experiment is often quite sufficient because his own experiences in the laboratory enable him to visualize it. But a lay audience has not this advantage. To the layman the difference between the description of an experiment and the actual witnessing of it is as great as the difference between looking at a foreign country on the map and visiting it; we grasp its geography in a far more vivid way when we have been to the place. One is struck again and again by the immense superiority, as judged by the effect on the audience, of a series of experiments and demonstrations explained by a talk over a lecture illustrated by slides. The Christmas Lectures to young people at the Royal Institution afford a good instance. It is surprising how often people in all walks of life own that their interest in science was first aroused by attending one of these courses when they were young, and in recalling their impressions they almost invariably say, not "we were told" but "we were *shown*" this or that. This impact of the witnessed experiment is all the more important because the popular talk is so dependent on emotional reactions. Students take notes, when attending a course, and colleagues listening to an account of research are alive to its bearing on their own work and see the printed account afterwards, so the context is more important to them than the manner of delivery. The final result of the popular talk is measured, however, by the extent to which the audience recalls it afterwards, and this fixation of the image is effected by arousing an emotional response of interest and thrill.

It is perennially surprising to find that it is the simpler experiments which have the warmest reception, especially if they can be done on a spectacular scale. The audience likes to see 'the works'. It is of little help to do something mysterious in a box which makes a pointer move over a scale. The simple experiment is effective because it can be grasped completely, and the members of the audience have the pleasurable feeling that it has become a part of their own experience. Again, there is an art in arranging an experiment so that it shall be æsthetically attractive. We instinctively recognize this when we say after a lecture, "That was a pretty experiment he showed". These may seem small points; but they are important. They may make the difference between a pleased and responsive audience, and one which is bored. If the listeners go away feeling that they have really understood what the lecturer was trying to explain, then they will come again for more. Non-scientists must not be left to feel that all science is too difficult to understand, otherwise they will shut their minds and think that science is for scientists only.

The other guiding principle of the popular lecture is that of starting with something with which the audience is thoroughly familiar in every-day life, and leading them further with that as a basis. The survey of the new country must be tied on to fixed points which are already in their minds. This is one of the most difficult tasks facing the popular lecturer. He may be honestly trying to avoid technical language; but it goes further than that. He has to put himself in the place of the intelligent layman and realize that ideas and experiences so familiar to him are unexplored country to his listener. This may seem to be a stressing of the obvious; but I venture to stress it because I have rather special opportunities to assess the effect of popular scientific talks, and they often pass completely over the heads of the audience because an otherwise excellent talk does not establish an initial *rapport* with the listeners' knowledge and experience.

There is nothing novel in these views, they are merely a recapitulation of the principles which have been preached and practised by all the great exponents of popular lecturing from Faraday onwards. It seems to me, however, that they have an important bearing in planning our strategy for a wider interpretation of science to the public. Merely talking and writing about the wonders of science can be very ineffective because the public is nowadays so bombarded with talks and articles on subjects of all kinds through so many channels. If our message is to be heard above the general noise-level, we must use the most powerful aid we have. The primary way to interest the public in art or music is to show pictures or arrange concerts, and lectures on art or music can only be appreciated when they are related to such first-hand impressions. The primary way to interest the general public in science is to show experiments and demonstrations, and so let them share in the thrill of understanding how things work, which is after all a good popular definition of science.

The staging of a demonstration lecture requires much organization. A simple experiment which takes a few minutes to show in the theatre may demand as many weeks of preparation. There must be a supporting background of technical staff, workshop, and demonstration apparatus of all kinds as well as a suitably fitted theatre, and if a worth-while proportion of the public is to be covered, it means a whole-time use of these facilities which is costly. The Royal Institution is now running a series of demonstration talks for boys and girls throughout the school year, in collaboration with the science teachers, at which large-scale experiments are shown which cannot easily be staged with school resources. An approximate estimate of the cost, based on the proportion of overhead charges allocated to the scheme, is £5,000 a year, which is defrayed by the generous assistance of industrial firms and other bodies which are interested in the venture. Some 16,000 tickets are issued annually. The young people come from an area which includes about one-quarter of the schools in England, and their keenness indicates that this is a very repaying way of using the resources. Some half-dozen such centres operating on a similar whole-time basis would cover most of Great Britain. Certain famous annual lectures sponsored by various bodies are by tradition the occasion for numerous carefully prepared experiments, and these lectures draw enthusiastic audiences. Television can, of course, be a powerful means of transmission ; but the laboratory resources must still be there behind the scenes for providing the programmes. My contention, therefore, is that merely increasing the number of talks and articles about science will not get us very far in interesting the general public, that on the other hand one gets the most rewarding response if one stages shows of experiments for them, and that if their interest is first so aroused, they will be much more able to appreciate the talks and articles.

OBITUARIES

Prof. D. R. Hartree, F.R.S.

Prof. D. R. Hartree, who died suddenly in Cambridge on February 12 at the age of sixty, had been Plummer professor of mathematics in the University since 1946. Before that he had spent fifteen years in Manchester, first as Beyer professor of applied mathematics and later as professor of theoretical physics. He was elected a Fellow of the Royal Society in 1932.

Hartree was born in Cambridge in 1897 and was seventeen years old when the First World War broke out. He served in the Munitions Invention Department and held a commission in the R.N.V.R. When the War ended, he returned to Cambridge to take the Natural Sciences Tripos. He became a Fellow of his own College, St. John's, and later migrated to Christ's College, where he held a fellowship for a short time before going to Manchester.

Some of Hartree's earliest work was on the propagation of radio waves in a magneto-ionic medium, and he wrote several important papers on this subject. His principal contribution to physics, however, was the development of the method of self-consistent fields for the computation of atomic wave functions. Early applications of wave mechanics had been to simple atoms such as those of hydrogen and helium, but Hartree saw a way of obtaining, by numerical means, wave functions for heavier atoms. He exploited this method with great vigour, and a long series of papers appeared in which Hartree and his collaborators presented the results of calculations for a large number of atoms.

Hartree's work on atomic wave functions led him to a more general interest in numerical analysis, and this eventually became his major preoccupation. To him numerical analysis was above all a practical subject and he brought the same kind of enthusiasm to computing as others bring to practical work in a laboratory. He always liked to tackle a new problem, and anyone who brought a problem to him would, as like as not, be given practical help as well as advice.

Although Hartree enjoyed computing—a little while before his death he claimed that he had some 10,000 hours of personal computing to his credit—he appreciated very early the advantages which might be obtained from mechanical aids. He was responsible for introducing the differential analyser into Britain, and the machine which, at his instance, was installed in the University of Manchester in 1935 was used to solve a wide range of problems. During the Second World War the machine was occupied with military problems of various kinds including, notably, an investigation into the mode of operation of the radar magnetron.

When the War ended, Hartree visited the United States to study the developments then going on in automatic digital computers. His practical experience of numerical analysis enabled him to make a distinctive contribution in this field and he rapidly became accepted as an authority. He was much in demand as a lecturer, and a course he delivered at the University of Illinois in the autumn of 1948 was published in book form.

When Hartree arrived in Cambridge in 1946, development work on an electronic digital computer was starting in the Mathematical Laboratory. Hartree associated himself with this project with characteristic enthusiasm and the Laboratory owes much to him for encouragement, advice and practical assistance. He continued his close association with the Laboratory until his death and took a prominent part in the running of successive summer schools in programme design and in the teaching for the diploma in numerical analysis and automatic computing.

Hartree did much to advance the interests of the Cavendish Laboratory, where he had his office. In particular, he was largely instrumental in reorganizing and improving the teaching of mathematics to science students, and in establishing theoretical physics as an optional subject in Part 2 of the Natural Sciences Tripos. In addition to his scientific interests, Hartree was a very keen musician, and played an important part in the founding of the Faculty of Music in the University of Manchester.

Hartree will be greatly missed by his many friends. He was the kindest and most unassuming of men, and endeared himself to all who worked with him.

M. V. Wilkes

Dr. C. J. Davisson

Physicists all over the world, and especially those of the older generation, will have heard with deep regret of the death on February 1 of C. J. Davisson.

Davisson is known best for his work on the diffraction of electrons by metal crystals, which established for the first time the wave character of free electrons and proved L. de Broglie's relation $\lambda = h/p$ between the wave-length λ and the momentum p of an electron. In fact, this work was the outcome of a long series of experiments started for quite a different purpose.

Davisson, who was born in Bloomington, Illinois, on October 22, 1881, took his degree in the University of Chicago in 1908. R. A. Millikan was there at the time and claimed with pride to have directed him towards physics. Davisson then went to Princeton, where he took his Ph.D., and his first published paper appeared in 1909 from Princeton. In 1911, working under O. W. Richardson, then a professor at Princeton, he published another paper on the emission of positive ions from heated salts of the alkali ion and established that they are singly ionized atoms of the metal. In the same year he married one of Richardson's sisters. He then went as instructor to the Carnegie Institute of Technology. His connexion with the laboratory where his life-work was done started as a consequence of the First World War. In 1917 he went to what is now the Bell Telephone Laboratories, then part of the Western Electric Company's organization, to take up a temporary post; he stayed there until 1946.

His war-time work was concerned with the physics of the then new thermionic valves and vacuum technique. After the War he continued to work on the fundamental principles of thermionics and was allowed a free hand in choosing his researches to an extent unusual in those days in an industrial laboratory. He was the first to show experimentally that the variety of Richardson's formula, which in fact makes the electron follow the Fermi–Dirac electron statistics (not then discovered), is preferable to the original form. He also did work which turned out to be of considerable commercial importance on oxide-coated filaments.

Davisson's discovery of electron diffraction arose from a study of the scattering of electrons, and the production of secondary electrons, from metals. The first paper on nickel, with C. H. Kunsman, appeared in *Science* during November 1921. It described surprisingly sharp peaks of reflected electrons which Davisson considered could be explained by scattering (classical, of course) from two shells of electrons. In 1925, after studying some other metals, he returned to nickel. Until then, the experiments had all been on ordinary polycrystallic metals; but by an accident the specimen became oxidized and in restoring the surface by heating was changed into an aggregate of only a few crystals. There was a complete alteration in the pattern of scattering and the former theory had to be abandoned. He was inclined at first to replace it by one of 'transparent directions' of the lattice; but, partly as a result of a visit to the British Association meeting at Oxford, he came to believe that the effect was connected with the new theories of de Broglie and Schroedinger. As a result of a careful search, he and Germer found the first electronic beams in positions which could be explained in this way on January 6, 1927. The consequences of this work of Davisson and Germer are well known, but it is not always realized what a supreme experimental feat these early experiments were. The slow electrons of the order of 150 volts which were used are most difficult to handle, and if the results are to be of any value the vacuum has to be what would still be considered good, and was then quite outstanding. In fact, very few experimenters have since been successful with the method; much faster electrons are used when electron diffraction is employed for the study of surfaces.

In 1937 Davisson shared with me the Nobel Prize in Physics for this discovery.

In the 30's Davisson was interested in electron optics, and with C. J. Calbick could claim the discovery of the principle of the electrostatic lens. During the Second World War he worked on the cavity magnetron. In 1946 he retired from the Bell Telephone Laboratories on reaching retiring age, and was appointed research professor in the University of Virginia and lived at Charlottesville until his death. He leaves a wife, three sons and a daughter. Among many other honours he was awarded the Hughes Medal of the Royal Society.

Davisson was a man of exceptionally lovable character. Slight in build and with a hesitant manner of speaking, which made him seem shyer than he really was, he had a delightful sense of humour and was full of fun. Though he worked most of his life in an industrial laboratory, he was essentially an individualist. Yet he had the reputation of being very accessible in the laboratory and most helpful to all who consulted him. Among those who had close contact with him at the Bell Laboratories are Lee Du Bridge, Merle Tuve, Philip Morse and William Shockley.

GEORGE THOMSON

Mr. J. L. Baker

JULIAN LEVETT BAKER was, when he commenced in 1900, the first chemist appointed to a London brewery. Born in 1873, he had trained at Finsbury Technical College and had worked as a chemist for the Beetroot Sugar Association before brewing became his life-work.

From the first, he energetically studied the many possibilities of improvement in brewing which science could suggest at that time, and in the course of his work he published some fifty papers—a number of them inspired by his original studies on sugars. In 1905, he also published a concise and readable book on "The Brewing Industry".

In 1904 he was joined by Henry Everard Hulton, and the two engaged in the work of the brewery and in numerous scientific studies. It was a memorable collaboration which lasted for thirty-four years until Hulton's death—at which time Baker wrote: "Throughout the long years no shadow was ever cast over an enduring friendship".

Indeed, all Baker's pursuits created something of a record for length. He was an original member at the formation of the Institute of Brewing in 1904 and was a vice-president for forty years (1918–58). He was a scientific editor for forty-two years—first of *The Analyst* (1907–20) and then of the *Journal of the Institute of Brewing* (1920–49); while his service with Watney, Combe, Reid and Co., Ltd., lasted for forty-six years.

His merits were recognized by the award in 1948 of the Horace Brown Medal of the Institute of Brewing.

Baker's interests and energies were not confined to brewing aspects of chemistry, for, besides his editorship of *The Analyst,* he was honorary secretary of the London Section of the Society of Chemical Industry from 1903 until 1909 and its chairman in 1919.

In his retirement, Baker, lovingly tending his garden, outlived his contemporaries to recall to later generations with graciousness and charm something of the marked individuality and wide culture which a band of young London scientists had displayed so outstandingly in the early part of this century.

He died on January 29. He is survived by his two sons and his daughter.

L. R. BISHOP

NEWS and VIEWS

Royal Geographical Society : Medals and Awards, 1958

H.M. THE QUEEN has approved the award of the Royal Medals of the Royal Geographical Society as follows : *Patron's Medal :* Dr. Paul A. Siple, U.S. Antarctic Expedition, scientific leader at the International Geophysical Year's South Pole Base (the "Amundsen–Scott" Base), 1957–58, for contributions to Antarctic exploration and research ; *Founder's Medal :* Sir Edmund Hillary, leader, New Zealand component, Commonwealth Trans-Antarctic Expedition, for Antarctic and Himalayan exploration.

The Council of the Royal Geographical Society has made the following awards : *Special Gold Medal :* Dr. Vivian Fuchs, leader, Commonwealth Trans-Antarctic Expedition ; *Victoria Medal :* Prof. Roberto Almagià, professor of geography, University of Rome, for contributions to geographical research ; *Murchison Grant :* Prof. E. G. Bowen, Gregynog professor of geography and anthropology, University College of Wales, Aberystwyth, for studies on the geography of Wales ; *Back Grant :* Ingénieur-en-Chef Bertrand Imbert, leader of the International Geophysical Year French Antarctic Expedition 1957–58, for contributions to Antarctic exploration and research ; *Cuthbert Peek Grant :* Dr. Peter H. Davis, lecturer in botany, University of Edinburgh, for botanical exploration in south-east Turkey ; *Gill Memorial :* Dr. M. J. Wise, Cassel reader in geography, London School of Economics, for studies in economic geography ; *Mrs. Patrick Ness Award :* Captain A. G. Bomford, R.E., chief surveyor, South Georgia Survey, 1955–56.

The last occasion on which a Special Gold Medal was awarded by the Society was in 1910 when it was given to Robert E. Peary, of the United States Navy, the first man to reach the North Geographical Pole ; previous British recipients were Captain Robert Falcon Scott, R.N. (in 1904), and Sir Ernest Shackleton (in 1909).

Fourth Artificial Earth Satellite (1958β)

As part of the scientific programme of the International Geophysical Year, another artificial Earth satellite was launched by means of a 'Vanguard' rocket of the United States Navy from the testing ground at Cape Canaveral, Florida, on March 17. The new satellite, named 1958β, consisting of an aluminium sphere 6·4 in. in diameter and of mass 3·25 lb., is revolving in an eccentric orbit, varying between 400 and 2,500 miles above the Earth's surface, in a period of 135 minutes. The inclination of the orbit to the ecliptic is at present unknown. The satellite is equipped with two radio transmitters ; one, powered by chemical batteries, broadcasting on a frequency of 108·00 megacycles per second ; the other, powered by solar batteries, operating on 108·30 megacycles per second. The third stage of the 'Vanguard' launching vehicle, a rocket some 4 ft. in length with a mass of about 50 lb., which ejected the sphere from its nose when it attained orbital velocity, is also circling the Earth about a mile from the satellite. It is hoped that this satellite will continue in its orbit for a number of years and afford excellent opportunities for continued observations of value to geophysicists.

Brewing Industry Research Foundation :

Sir Ian Heilbron, D.S.O., F.R.S.

SIR IAN HEILBRON, who is retiring from the post of director of the Brewing Industry Research Foundation, Nutfield, Surrey, has held many distinguished academic appointments. He was professor of organic chemistry in the Imperial College of Science and Technology, London ; and also for some years a member of the Advisory Council of the Department of Scientific and Industrial Research, of which he became chairman in 1953. At the time of his appointment to the Foundation in 1948, the brewing industry had decided to start a central research station, and it fell to Sir Ian to select the site, and to adapt Lyttel Hall, the Victorian property chosen at Nutfield, to meet the requirements of up-to-date research laboratories. This he did with conspicuous success and the Foundation is now a notable example of a modern research station. Sir Ian's reputation as a scientist and in the sphere of research, in which he had rendered distinguished service on a number of departmental and national committees, enabled him to collect around him a band of first-class scientists, who quickly put the Foundation into the top rank of brewing research bodies in Europe, and extended its reputation to the United States. Not the least of Sir Ian's achievements has been that he has succeeded in keeping constantly before his staff, and before the industry, the ultimate practical applications of the fundamental research carried out at the Foundation.

Dr. A. H. Cook, F.R.S.

DR. A. H. COOK has been appointed director of the Brewing Industry Research Foundation at Nutfield at the age of forty-six in succession to Sir Ian Heilbron. Dr. Cook gained the Ph.D. degree for research in organic chemistry at the Imperial College of Science and Technology, London, and after a further period of study at Heidelberg, worked for some time in the field of dyestuff chemistry with Imperial Chemical Industries, Ltd. In 1937 he joined the staff of the Imperial College where, with Sir Ian Heilbron, he did notable work on the chemistry of penicillin. In 1946 he was appointed reader and assistant professor of organic chemistry at the Imperial College, and in 1951 he was elected to Fellowship of the Royal Society. Since 1949 he has been assistant director of the Brewing Industry Research Foundation under Sir Ian Heilbron.

The World and the Observer

IN his broadcast talk, "The World and the Observer", printed in *The Listener* of February 6, Lord Russell investigates the relation between our sensory experiences of material things and the theories of the natural sciences, in particular of physics, concerning the ultimate nature of physical reality. Primary particles such as electrons cannot be perceived, and are quite unlike the sort of objects which we can perceive. Russell's approach to the problem draws on physics, physiology, psychology and logic. His thesis may be summarized in three points. First, the entities dealt with by mathematical physics are "constructions composed of events and taken as units for the convenience of the mathematician". Secondly, everything that is directly perceived is private to the perceiver; it is an occurrence in the brain of an individual. Thirdly, these occurrences are the effects of external causes, the real nature of which cannot be certainly known. As Russell says, these doctrines have not met with great favour from other philosophers. The short space of a broadcast talk is scarcely sufficient to deploy all the arguments and qualifications necessary for a systematic defence of such general and far-reaching theories. One sentence is rendered unintelligible in *The Listener* by the misprint of 'casual' for 'causal', and 'precept' for 'percept'.

The Isaac Newton Telescope and the Navy Estimates

Questioned in Committee of Supply on the Navy Estimates under Vote 6 (Scientific Services) in the House of Commons on February 13 regarding the stoppage of work on the Isaac Newton telescope at the Royal Greenwich Observatory, Herstmonceux, the Civil Lord of the Admiralty, Mr. T. G. D. Galbraith, agreed that the telescope, the purpose of which is to extend the range of astronomical and astrophysical research, is of the greatest importance to the nation. Its cost is being shared between the Admiralty and the Treasury, but after £28,000 had been spent on primary design and study, of which £14,000 had come from the Admiralty, the project has now been suspended in view of the present financial stringency. Mr. Willis said that last year the expenditure was £30,000 and in the previous year £51,000, and he suggested that the stoppage gave point to the recent criticism of the Committee of Public Accounts. Mr. Galbraith said he could not, off-hand, confirm or deny these figures. As regards the International Hydrographic Bureau, while, as stated by Mr. Willis, in the past three or four years sales of charts had increased to 350,000, the 45 per cent increase in income was due partly to increases in price. The reduction in staff was due to the general need to economize. On the expenditure for scientific services generally, in the past two years the numbers of scientific and experimental personnel and of ancillary staff have fallen substantially, and research and development contracts have also generally decreased. The cuts, he said, had not affected important work like the development of nuclear propulsion, on which the Admiralty is working in very close co-operation with the Atomic Energy Authority.

Foundation for Mutual Assistance in Africa South of the Sahara

In a written reply to Colonel T. V. H. Beamish in the House of Commons on March 10, Mr. Ian Harvey, Joint Under-Secretary of State for Foreign Affairs, said that he had represented the United Kingdom at the Conference at Accra on February 19 and 20, when the Foundation for Mutual Assistance in Africa South of the Sahara was inaugurated. The member governments were those of Belgium, France, Portugal, the United Kingdom, the Federation of Rhodesia and Nyasaland, Ghana, Liberia and the Union of South Africa, but other countries and territories in Africa south of the Sahara would be eligible for technical assistance under the scheme. A United States observer had been present at the Conference, but there was no commitment on the part of the United States Government. The technical assistance would take the form of the supply of experts, advisers and instructors to countries in the region, the training of personnel from the region and the supply of equipment for training purposes, and it would be arranged unilaterally following the practice of the Technical Co-operation Scheme under the Colombo Plan. The small secretariat of the Foundation would act as a clearing house between Governments for requests for assistance and offers. The House of Commons would be asked to approve new expenditure of £20,000 by the British Government for such assistance during the next financial year.

Chemical Engineering in a University

Prof. P. V. Danckwerts, recently appointed to the chair of chemical engineering science in the Imperial College of Science and Technology, London, delivered his inaugural lecture entitled "Chemical Engineering in a University" on November 12. He emphasized that a university does not turn out chemical engineers and that its function is to explain to students what a chemical engineer may have to do, to teach them the basic principles on which chemical engineering depends and how to apply them and, above all, to train them to think for themselves. By way of illustration he discussed several chemical engineering processes broken down to show their complicated nature, and the scientific subjects with which it was necessary to be acquainted before trying to build them up. Since, moreover, the practice of chemical engineering is often in advance of the theory, it is imperative for a university to maintain the closest possible contact with industry. Dealing with the difficult question of research, Prof. Danckwerts maintained that, although desirable, research is not an essential part of university training. Certain types of research, such as process development, are, in many cases, unsuited to a university laboratory, owing to the difficulty of working on a sufficiently large scale; but there is a wide and important field in "trying to get a deeper insight into the mechanism of industrial processes by looking at them with a scientist's eye". Examples of possible problems followed, and of particular interest were those dealing with 'scaling up'. Prof. Danckwerts did not venture to tackle the most difficult problem of all: Where is the teaching staff to come from? But perhaps he regards this as outside the scope of his subject. As the first of a series of inaugural lectures to be published by the Imperial College, Prof. Danckwerts's address has now been printed ("Chemical Engineering in a University": Inaugural Lecture by Prof. P. V. Danckwerts. Pp. ii+10+4 plates. London: Imperial College of Science and Technology, 1958. 5*s*.), and will be found illuminating and suggestive by all interested in engineering education and its products.

Palaeontology

Early in 1957, a group of British palæontologists met in London to discuss the formation of an association to further the study of palæontology by the holding of meetings in London and various other centres, and the publication of a journal. The inaugural meeting of the Palæontological Association was held in February 1957, and we now welcome the new journal, *Palæontology*, which made its appearance last November and is to be published half-yearly. The journal is crown quarto in size, and Vol. 1, Part 1, contains eighty-six pages and fourteen collotype plates, the production being of the high standard associated with the Oxford University Press. Contributions will, it is hoped, cover all aspects of palæontology, and included in the first number are articles on the true *Rhynchonella*, Upper Viséan goniatites, the type-species of *Girvanella*, the Cretaceous ammonite *Leymeriella*, *Encrinurus multisegmentatus* and its allies, and descriptions of a new genus of foraminifer and a new Tertiary calcareous alga. The membership subscription is two guineas annually (the price per part of the journal is 35*s*. or 5.20 dollars). The president of the Association is Dr. R. G. S. Hudson, and the treasurer Dr. W. S. McKerrow, University Museum, Oxford.

Evolution

It has been said that the greatest and most enduring monument to the late Dr. O. G. S. Crawford is the journal *Antiquity*, which he inaugurated thirty-one years ago and edited up to the time of his death. He planned his last number, which appeared posthumously in December 1957 (pp. ii + 185–257 + 5 plates. London: Phoenix House, Ltd., 1958. 10*s*. 6*d*. net), as a special evolution number to commemorate the Darwin–Wallace centenary, and it is particularly noteworthy for its frontispiece of a hitherto unpublished sketch of Charles Darwin made in 1855. The number includes a concise and authoritative summary of human evolution by R. Singer, a well-reasoned statement by K. P. Oakley on the evidence for the earliest stages of tool-making, and short articles by the late Prof. Gordon Childe on "The Evolution of Society", and by L. A. White on "Evolution and Diffusion". Another essay, highly appropriate because of its relation to some of Darwin's own studies, is by R. J. C. Atkinson on "Worms and Weathering"; it is the aim of this essay to direct attention to disturbances of the soil produced by worms which, unless taken into careful account, may tempt archæologists to base conclusions on what is really a falsified stratigraphy.

Cleaning Inscriptions

The *Museums Journal* for December 1957 includes an article by Dr. David Smith concerning the cleaning of inscriptions and sculptures in sandstone. The objects comprised altars, military inscriptions, tombstones and sculptures of the Roman and Anglian periods previously housed in the Black Gate Museum in Newcastle upon Tyne. They were cleaned in preparation for exhibition in the new museum erected by the University of Durham. The first step was to remove the surface dirt with a gentle spray of water directed from a rubber hose. For some of the worst cases this was the maximum treatment that the stone could stand. In other cases experiments were conducted with household detergents, dilute hydrochloric acid and fibre scrubbing brushes with hot water; and steel wire scrubbing brushes were also used with much success. This may seem a drastic method, but providing the surface of the stone is sound and the work is done under a constant flow of hot water, it has been found that no harm results. Each stone when completely cleaned was washed and maintained at a fairly constant temperature of 55° F. in another room. After about three months, a colloidal solution of silica in alcohol (ethyl silicate) was applied. This reinforced the natural bond of the stone, hardening it and reducing its porosity without completely sealing it or affecting it in any other way.

Remanent Magnetism

Study of the natural remanent magnetism of rocks is becoming a familiar method for determining the direction of the Earth's magnetic field at past stages in its geological history, and has led to interesting speculations about the wandering of the geomagnetic poles or of the continents themselves. An alternative use for measurements of remanent magnetism, namely, the determination of the temperature of formation of pyroclastic deposits, is described by Shigeo Aramaki and Syun-ito Akimoto in the *American Journal of Science* (255, 619; November 1957). The method depends on the fact that if all the fragments composing a deposit of this kind maintained a temperature above the Curie point of the constituent ferromagnetic minerals during emplacement, and cooled below this point only after coming to rest, their thermo-remanent magnetism must show a uniform orientation parallel to the geomagnetic field at the time and place of cooling. If, on the other hand, the fragments had already fallen below the Curie point before settling, the natural remanent magnetism of the fragments will have random orientations. Using this criterion, the authors have been able to distinguish between *nuée ardente* deposits and mud-flow deposits associated with several Japanese volcanoes and formed at various periods from recent historical to late Pleistocene times.

Wilmot Breeden Fellowships

The Wilmot Breeden Group of Companies, the manufacturing interests of which include motor-vehicles and gas-turbine components, hydraulics and electronics, are sponsoring two fellowships, each worth £1,000 per annum, one at the University of Birmingham and the other at the Birmingham College of Technology. Successful candidates will divide their time between the University or College and the Company. The fellowships will be advertised every year in March, in odd years in association with the University and in even years in association with the College. Each fellowship will normally be held for a period of two years. Candidates, who should have an honours degree of a university in the British Commonwealth, a diploma in technology, or an equivalent qualification, should normally have had two or three years experience of research or industry. An application for a fellowship should outline a two-year programme of research on which the candidate seeks to work. Inquiries can be addressed to the Secretary, Wilmot Breeden (Holdings), Ltd., Amington Road, Birmingham 25.

Society of Analytical Chemistry: Officers

The following officers of the Society for Analytical Chemistry were recently elected for the forthcoming year: *President*, J. H. Hamence; *Past-Presidents serving on the Council*, D. W. Kent-Jones, J. R. Nicholls, G. Taylor and K. A. Williams; *Vice-Presidents*, N. L. Allport, R. C. Chirnside and A. A. Smales; *Honorary Treasurer*, A. J. Amos; *Honorary Secretary*, R. E. Stuckey; *Honorary Assistant Secretary*, S. A. Price; *Ex-Officio Members of Council* (chairmen of Sections): A. N. Leather (North of England Section), Magnus A. Pyke (Scottish Section), S. Dixon (Western Section), R. Belcher (Midlands Section), D. F. Phillips (Microchemistry Group), R. A. C. Isbell (Physical Methods Group) and S. K. Kon (Biological Methods Group).

American Phytopathological Society

The American Phytopathological Society is celebrating its fiftieth anniversary this year, and a series of outstanding symposia by internationally-known scientists is being presented at the meeting of the Society with the American Institute of Biological Sciences in August. A book of approximately 1,000 pages entitled "Plant Pathology—Problems and Progress 1908–1958", containing more than sixty symposium papers, will be published by the American Phytopathological Society in the winter of 1958. The papers in this volume are primarily basic in content and apply to many phases of the biological and physical sciences. Further information can be obtained from the American Phytopathological Society, P.O. Drawer 1106, New Haven 4, Conn.

University News :

Birmingham

Prof. F. H. Garner's tenure as professor of chemical engineering and head of the Department of Chemical Engineering has been extended for two years to 1960. The title of reader in mechanical engineering has been conferred on Dr. B. N. Cole, senior lecturer in mechanical engineering; and the following appointments have been made: Dr. R. D. Peacock and Dr. J. Burdon, to be lecturers in chemistry; T. R. Bott, to be lecturer in chemical engineering; D. I. Rees, to be J. Lyons research fellow in analytical chemistry; Dr. D. A. Heath, to be lecturer in pathology; and W. Marsh, to be lecturer in orthodontics.

The new Chemistry Block (the first stage of which should be completed in 1960) is to be named the Haworth Building to commemorate the late Sir Norman Haworth, who was Mason professor and director of the Department of Chemistry in the University during 1925–48.

London

Dr. S. R. Sparkes, reader in civil engineering at the Imperial College of Science and Technology, has been appointed to the chair of engineering structures tenable at that College; and Mr. G. R. Hall, acting principal scientific officer at the Atomic Energy Research Establishment, Harwell, has been appointed to the readership in nuclear technology tenable at the Imperial College.

Announcements

Prof. C. A. Coulson, Rouse Ball professor of applied mathematics in the University of Oxford, will deliver the 1958 Eddington Memorial Lecture in Cambridge, at the Arts School Lecture Theatre, Bene't Street, on April 21 at 5 p.m.; his subject will be "Science and the Idea of God".

A symposium on Molecular Structure and Spectroscopy will be held in the Department of Physics and Astronomy, Ohio State University, during June 16–20. There will be discussions of the interpretation of molecular spectroscopic data as well as methods for obtaining such information. Accommodation will be available for those who wish to reside on the campus during the meeting. Further details can be obtained from Prof. R. A. Oetjen, Department of Physics and Astronomy, Ohio State University, Columbus 10, Ohio.

The 1958 Microscopy Symposium, the fifth of these symposia, will be held in Chicago during June 9–12 and will include sessions on instrumentation, electron microscopy, X-ray microscopy, autoradiography, medical and biological applications, fibres and plastics, forensic microscopy and structural materials. Exchange of ideas and techniques are encouraged in an informal atmosphere. Further information can be obtained from W. C. McCrone, jun., Walter C. McCrone Associates, 500 East 33rd Street, Chicago 16, Illinois.

The Postal and Telecommunications Group of the Brussels Universal and International Exhibition is organizing an international conference on "Solid State Phenomena in Electronics and Telecommunications" to be held in the University of Brussels during June 2–7. Three major subjects will be treated at this conference: semi-conductors, magnetic materials and photo-sensitive and luminescent materials. Prospective authors of papers in those fields are invited to notify the organizers as soon as possible. Further information can be obtained from the Hon. General Secretary, Société Belge de Physique, Loverval, Belgium.

A conference on "Noise", with particular reference to industry, organized by the British Occupational Hygiene Society, will be held at the Canterbury Hall, Cartwright Gardens, London, W.C.1, on April 1. The conference is open to non-members of the Society on payment of a registration fee of one guinea. Mr. T. E. Cawthorne (King's College Hospital) will discuss the physical disturbances produced by excessive noise; Dr. T. S. Littler (Wernher Research Unit on Deafness) will describe the techniques of measuring noise; Dr. A. E. Carpenter (Applied Psychology Research Unit of the Medical Research Council) will deal with the disturbance of mental performance caused by noise; and the suppression of noise will be dealt with by Mr. N. Fleming and Mr. W. C. Copeland (National Physical Laboratory). Further details can be obtained from the hon. scientific secretary, Dr. D. Turner, Associated Ethyl Co., Ltd., Ellesmere Port, Cheshire.

The Non-destructive Testing Group of the Institute of Physics has organized a joint conference with the Société Française de Métallurgie, to be held in Paris during June 16–20. The theme is to be the utilization of physical properties for studying the relationships between the constitution, structure and service behaviour of metals, and there will be both French and English chairmen at each discussion session. The conference, for which there is no fee, is primarily intended for members of the Institute of Physics, but there will be limited accommodation for non-members. A parallel programme, including visits to Malmaison and St. Germain, is being arranged by the French Metallurgical Society, and members' ladies are expressly invited on this occasion. Those who wish to attend should apply, before March 24, on forms obtainable from Mr. L. Lawrence, Institute of Physics, 47 Belgrave Square, London, S.W.1, to whom all inquiries should be addressed.

Erratum. In the article by Dr. E. B. Kraus entitled "Recent Climatic Changes" in *Nature* of March 8, p. 666, the formula in the second paragraph is incorrect; for $y(n) = 100 \sum_{l=1881}^{n} \left(\frac{r_l}{\bar{r}-1}\right)$ read $y(n) = 100 \sum_{l=1881}^{n} \left(\frac{r_l}{\bar{r}} - 1\right)$.

TECHNOLOGICAL EDUCATION IN BRITAIN

THE development, up to July 1957, of courses leading to the new Diploma in Technology is recorded in the first report of the National Council for Technological Awards, which was published on November 21*. At that date there were 965 students in thirty-seven courses leading to the new award. The report gives a full list of the courses now in progress which have been approved; these include applied chemistry, applied physics, applicable mathematics, applied pharmacology, applied biochemistry, aeronautical engineering, mechanical engineering, civil engineering, electrical engineering, and production engineering. Of 123 applications which had been received, 83 had been considered by July 31, 1957, and of these 49 were accepted and 34 rejected. The 49 accepted comprised 29 existing courses and 20 proposed new courses.

The report opens with a brief review of the events leading up to the establishment of the National Council, with its two boards of studies, one for engineering and one for technologies other than engineering. The constitution of the subject panels which deal with individual technologies is then mentioned and the procedure for the consideration of courses is described. The written submission from a college is considered by the appropriate subject panel, and, generally, the college is visited by members of the Council, the object of the visit being to inform the Council of the setting in which the course would be conducted, to meet the principal of the college and his staff, to see the equipment and accommodation available, and in general to enable the Council to form a better assessment of the position than could be done on the basis of the written application alone.

Several of the important features of the scheme receive comment in individual paragraphs of the report. Recalling that the standard of admission to courses is either five subjects in the General Certificate of Education, of which two appropriate to the course must be at Advanced Level, or a 'good' Ordinary National Certificate, the comment is made that the Council has not attempted to establish a definition of 'good' for this purpose, but has considered individually the proposals put forward by colleges. It is pointed out that there is also provision for the entry of students not possessing these qualifications but who have completed successfully a course of preliminary training.

Dealing with syllabuses, the report reiterates that, in all courses approved, the study of fundamental science and technology and their application provides a course of disciplined study fully equivalent to that leading to a university honours degree. The interesting comment is made in this section that in relation to some of the courses which the Council has rejected the weakness has been one, not of inadequate syllabus content, but of overcrowding the syllabus, resulting in an excessive number of hours in the week assigned to formal classes.

The importance of providing a reasonable amount of time for private study is emphasized and it is remarked that few colleges have adequate space available for this purpose. This, it is implied, is associated with inadequate library facilities—a situation which is being rectified.

Specific reference is made to the 'project' as an important part of the work of the course in the final year, and it is suggested that the project may well serve as a link between the industrial training and the subjects studied. Liberal studies which might serve to give the student some appreciation of the social and economic significance of the technology he is studying are expected to form part of the curriculum and should constitute subjects which are examined. It is recognized that the best methods of incorporating such liberal studies are still very much a matter of experiment, and an appreciative reference is made to the serious way in which colleges are tackling the pioneer work to be done in this matter.

In regard to staff, special reference is made to the report of the Special Committee on the Supply and Training of Teachers for Technical Colleges. Of particular urgency are the matters of reducing the excessive teaching load carried by many teachers in technical colleges, the provision of adequate research facilities and of adequate research assistance and clerical assistance. Associated with these are several other recommendations from the report, among which may be mentioned the proposal that "senior members of industrial staffs should be given a special status in colleges permitting them to be closely identified with all the academic activities of the college" and the "appointment of representatives of industry and commerce to college Governing Bodies as a means of ensuring the effectiveness of the college's work and of helping to secure part-time staff from industry".

Another of the fundamental principles upon which the Diploma in Technology is based is restated in the report in the words: "The Council regard a course leading to the Diploma in Technology as a complete entity, the industrial training being just as much a part of the course as the academic study". Full and wholehearted co-operation between college and industrial firm is essential if works experience and academic studies are to be genuinely complementary. The view is expressed that such close and effective association may well be difficult to achieve when a number of small firms are involved, but its attainment is of the utmost importance as it constitutes one of the most valuable—and indeed unique—features of the scheme. Associated with this is the problem of maintaining an appropriate amount of study during the works periods.

The Council is confident that the substantial building programme now in progress will remove the majority of the many deficiencies in accommodation found in colleges. These deficiencies have in the main concerned amenities for student social activities, libraries, accommodation for project work and private study, and for research by staff. Residential accommodation for students is regarded as essential, but the initial absence of such facilities has not prevented the recognition of courses.

The main body of the report concludes with a statement that the Council has set up a special committee to make recommendations as to what postgraduate award the Council should offer. Six appendixes provide information concerning the governing body, boards of study, courses in progress which have been recognized and new proposed courses, together with notes about the subjects of courses approved and rejected. The last two appendixes state the examination arrangements and give the decisions of the Council concerning the minimum length of a sandwich course, and conditions for exemption from the first year of the course.

---

* National Council for Technological Awards. Report for the period December 1955 to July 1957. Pp. 20. (London: National Council for Technological Awards. 1957.)

It is evident from the report that the response of technical colleges to the institution of the new award has been excellent. The relatively high rate of rejection for courses offered has been due to the insistence of the Council on the maintenance of fully adequate standards, a matter of paramount importance in the establishment of the standing of the new award.

Enrolment of approximately one thousand students in the courses recognized up to July of last year represents a substantial and encouraging start to a project which should make a great contribution to meeting the need of Britain for additional technologists. Although the appendixes to the report give considerable detailed information about the position, one vital factor is absent, namely, the distribution of students in relation to their method of satisfying the entrance requirements. In assessing the net gain, the real criterion is that of the sources from which the men are drawn, and it is to be hoped that in future reports this information will be presented.

SCIENCE EDUCATION IN MALTA

DURING Malta's tenth education week, which was organized by the Malta Union of Teachers during May 4–11, 1957, Prof. G. P. Xuereb, dean of the faculty of medicine and surgery in the Royal University of Malta, discussed the place of science in the Maltese educational system.

There is in Malta an acute realization of the fact that changes are necessary in the educational system. The social environment has changed, and educational methods have become unrelated to the social background. There must be an intimate and indissoluble connexion between the pattern of an educational system and the social order for which it is preparing the citizens.

One of the principal causes of the maladjustment between Maltese education and the country's needs lies in the fact that the new scientific knowledge, from which social changes have sprung, is incorporated very imperfectly in the educational system.

The majority of Maltese educated men and women are unaware of the way scientific discovery has shaped society in the past and of the way in which it might change it in the future. Inadequacy of science teachers is imperilling the introduction of the sixth forms in school. The Civil servant is having to face the administration of industry, trade development, public health, statistics, technical education, labour and social services created by forces that his education did nothing to lead him to understand. Everywhere there are improvized methods, because education has given no training.

Scientific studies are not providing the social stimulus and the intellectual training which they should. Judged by the actual hours of teaching, science is still a minor subject in general education. Many teachers still believe that science should not be taught as part of a general education—a belief disguised laconically by the statement that they wish to avoid "premature specialization".

The content of the science courses also leaves much to be desired: the course must be coherent so that everybody realizes the connexion between the successive parts of his science work. Instead of coherence there is a strong bias towards physics—and physics in its most arid form. Chemistry is not yet established. Biology, far from being taught as the natural history of animals and plants, is 'nature study' and is hurriedly jostled out of the curriculum when it arouses the inborn curiosity of youth. Science is being taught as a collection of laws and facts rather than as a constantly growing body of knowledge with social implications of vital importance. The social repercussions of science are relegated to a few isolated industrial applications. Briefly, science is presented as a dead body of facts, rather than as a living cultural and social force.

When these boys go to the Royal University, a course in general science is quickly prescribed for the lawyers, legal procurators and theologians of to-morrow. In this course the lecturers ensure that the students learn to believe the authority of the master or text-book and to reproduce the text when asked. These students are confined to the lecture room and are never referred to the laboratories.

The science courses are not much better themselves. Science students spend two years at the University acquiring the basic theoretical and practical knowledge which they should have more appropriately gathered in the secondary schools. Then, when they are ready to absorb some scientific method, they are passed on to the intermediate course in medicine, pharmacy, architecture and engineering. In medicine considerable time is devoted to introducing them to the sequence of hypothesis followed by experiment or observation and then analysis. Is it surprising that nearly 70 per cent of science students fall by the wayside and that only 30 per cent obtain a medical qualification ?

In the past three years the University has taken certain steps to ensure that science is brought into closer relationship with the needs of life. A four-year course for Civil servants has been instituted leading to a diploma in social and political administration. Scholarships in biology, chemistry and physics have been provided, and three Maltese graduates are now at Oxford and London taking the honours school in these specialities before appointment to lectureships in science. The University of Malta will shortly be requiring matriculation in chemistry and in physics or biology from prospective science students. The University has drawn up plans for reform in the course of pharmacy. The libraries have been put on a scientific basis, science laboratories are now completed and funds have been secured for the building of a medical school. These measures are a beginning: they will contribute greatly towards bringing the Maltese educational system into line with a changing social environment.

MANAGEMENT DEVELOPMENT

At a conference organized by the British Institute of Management at Harrogate during January 22–24, more than a hundred representatives from leading industrial organizations in Britain discussed the finding and development of managers for industry.

To open the conference, Mr. E. F. L. Brech, of Urwick, Orr and Partners, examined the motives which cause young men to choose a managerial career. The goal could be money, the idea of power, prestige, or a wish to cover up the man's sense of inferiority. Mr. Brech suggested that these reasons are inadequate. The essence of management is responsibility for a social task, and the better educated mind should be attracted to management with the offer of a satisfying social job rather than for the financial return.

He wondered whether the advertisements selling the idea of a big and lucrative future in management were carrots to draw in bright young men who would not be given a chance to get ahead. Many men now in top managerial posts should not be there, and firms should keep their eyes open and remove incompetent men before they got too far. The responsibility of management is to do the job efficiently and economically. Good human relations lead to good morale and so help to achieve this end.

Here, Mr. A. Brown, administration and personnel director, Mars, Ltd., suggested that all companies should adopt an appraisal system to ensure that all human resources in the company are looked at systematically at least once a year. The right man, the best man for the job, should be sought within and without the company.

If the company needs a 'go-getter', then he should be sought. If the company needs a systematic, conservative type, he should be looked for. Small and medium-sized firms must often rely on large firms to train managers who will either find inadequate or too distant scope in those firms and seek work in the smaller company with its close relationships and opportunity for wide experience.

When selecting men as managers there must be not only a job specification but also a full definition of the requirements of the job in relation to the organization, its personnel and future planned development. It is desirable to know who the man will work with. Is a systematic or intuitive approach required in the job as envisaged? These are the kind of facts which should be known but rarely are.

If the company has a natural successor for an appointment, it should dispense with elaborate selection methods. If the company is satisfied that it has the right man after examining all information and records, the selection should be made there and then.

Mr. W. W. Ferguson, of James Williamson and Son, Ltd., suggested that, to find the right man, the old Army custom of making men into acting temporary unpaid lance-corporals should be tried on the shop floor. In this way, argued Ferguson, it could be discovered whether the prospective foreman was a good leader and, by letting him work with a carefully chosen foreman, he could be seen in action. If he were satisfactory, all would be well; if not, he could be returned to his previous job.

This assumption was not generally accepted. One or two delegates supported Mr. Ferguson, but many others rejected his plan as impractical. Most of the delegates felt that in industry it was no easy thing to lower a man's status after raising it, and that the temporary foreman would suffer as he could have no real authority during his trial period.

In an informal discussion, the conference considered a suggestion that the end of National Service would be the end of an interlude which did much useful work in disciplining the nation's industrial recruits. More than one speaker claimed that industry could get along quite well without this service, and that it could undertake its own teaching of discipline and training of apprentices.

One of the general conclusions emerging from the conference was that management development is supported only by a representative, sincere and progressive slice of British industry. More than once voices were raised to ask whether top management—the policy makers and leaders of industry—was yet sufficiently convinced of its practical value.

Examples were given of firms with comprehensive management development programmes sympathetically encouraged by the men at the top: so were more cynical views that top management thought such programmes a waste of their valuable time.

T. H. Hawkins

ELECTRON MICROSCOPISTS

At the fifteenth annual meeting of the Electron Microscope Society of America, which was held at the Massachusetts Institute of Technology on September 11, 1957, the president, Dr. J. H. L. Watson, head of the physics department of the Edsel B. Ford Institute for Medical Research (Henry Ford Hospital, Detroit 2, Michigan), gave a summary of the results and conclusions of a survey which he had recently conducted on the subject of what was expected professionally of a trained electron microscopist. The survey was made by questionnaire and letter addressed to two hundred electron microscopists and directors or supervisors of laboratories in which electron microscopy is used. One hundred and thirty-nine answers and opinions were received, but despite the diverse fields of application in the various institutions the replies showed a surprising unanimity.

A good laboratory attitude, a co-operative personality, scientific imagination, and patience, were the particular personal qualities required. Familiarity with the particular field of application, in addition to electron microscopy, was stressed, as was also the importance of ability to inform others clearly and concisely of the work in progress. No desire was expressed by the biologists or non-biologists for a difference in training of scientists for electron microscopy in their respective spheres, except that the non-biological institutions mentioned that especial emphasis should be given to optical microscopy. The replies included eleven from sources outside the United States, but their requirements were almost identical with those from the industrial non-biological institutions, differing only in that 'skill in photography' was asked for in preference to 'knowledge of allied instruments'.

In almost all cases the duties expected of a trained electron microscopist were expected in a high order of perfection—not just to maintain the instrument, but to maintain it 'at its peak'—thus demanding a maximum of experience and training in the field and indicating a preference for postgraduate training.

Dr. Watson referred to the great shortage of research electron microscopists in the United States of America and stated that a strong plea could be made for graduate university courses in electron microscopy where men from diverse fields could be trained in the fundamentals of the subject and conduct electron microscopical research in their respective fields leading to postgraduate degrees.

S. WEINTROUB

FREEZING FISH AT SEA

A PRIMARY aim of the work at the Torry Research Station of the Department of Scientific and Industrial Research is the improvement in quality of fish as sold to the consumer. Particular attention has been paid to the problem of fish, principally cod, caught in Arctic waters, since the earlier part of the catch may be some twelve days old when it is landed. During the voyage the fish are stowed in holds in crushed ice, and it is obvious that the quality at landing could be markedly improved if the fish were quick-frozen soon after catching. "Report on an Experiment into the Freezing of Fish at Sea" (pp. 65+6 plates. London: White Fish Authority, 1957. 5*s.*) is a record of an extensive and impressive large-scale experiment to examine the practical feasibility of such a scheme of quick-freezing at sea. The technical developments were undertaken by the Department of Scientific and Industrial Research, and in the field work the White Fish Authority and the trawler owners gave full co-operation.

Five main phases of the technical work are fully described: (1) the experimental development in the Torry engineering laboratories of a suitable type of freezer for whole cod; (2) the sea-trials of a prototype freezer in the Station's motor fishing vessel; (3) collection and analysis of operational data on fourteen typical trawler trips to northern waters, to provide a design basis for a full-scale plant; (4) the construction and shore testing of the full-scale freezing plant and the conversion of a typical trawler, *Northern Wave*, to take the installation; (5) the results of the eight experimental voyages with the freezing plant in action.

The freezing plant has a capacity of about 8 tons of fish per day and roughly 23 per cent of all fish caught was quick-frozen. Freezing was effected by direct-contact plates through which refrigerant at − 40° F. was circulated, and the frozen blocks were stored at − 20° F. in a specially installed cold store.

Details are given of the marketing experience and reaction to the product, and the financial and economic implications are summarized. The scale of the experiment was not large enough to permit of firm conclusions on all these points, but the findings should be of marked assistance to trawler owners contemplating the adoption of freezing at sea. The outstanding feature of the experiment was the successful performance of the freezing equipment under all weather conditions, and the technical feasibility of the project was amply demonstrated.

CARTOGRAPHY

THE first volume of the official records of the first United Nations Regional Cartographic Conference for Asia and the Far East consisted of the report of the Conference. This has now been supplemented by a second volume*. Of this, the first 22 pages, or about one-sixth, consists of summary records of the discussions, which took as their starting point a recognition that "accurate maps are a prerequisite to the proper development of the world resources which in many cases lie in relatively unexplored regions", and that topographical mapping must necessarily precede geological or other specialized surveys. Delegates were concerned largely with the need of the less-developed countries for technical assistance in both survey and map compilation; and with the means by which publication of further sheets of the International Map of the World on the Millionth Scale might be encouraged. The "Technical Papers" follow and vary from an account of the status of publication of the International Map accompanied by communications on its future from various interested parties to descriptions of some of the most recent developments in survey methods.

The report on the "International Map of the World on the Millionth Scale"* is, except to the cartographically well informed, a most misleading document. It misleads particularly by its index map, which conveys the impression that the Map itself is well on the way to completion. This is far from being the case, and since it is important that scientists generally should be aware of the realities of the situation regarding this basic map of the world, it is well to recall the history of this project.

The original proposal for an international map of the world on a scale of 1 : 1 million (about 16 miles to 1 in.) was made by Prof. A. Penck at the International Geographical Congress in Berne in 1891. It

* United Nations Regional Cartographic Conference for Asia and the Far East, 15–25 February, 1955, Mussoorie, India. Vol. 2: Proceedings of the Conference and Technical Papers. Pp. x+133+2 maps. (New York: United Nations; London: H.M. Stationery Office, 1957.) 1.50 dollars; 11*s.*; 6.50 Swiss francs.

* International Map of the World on the Millionth Scale: Report for 1955 prepared by the Secretariat. Pp. iii+84+1 map. (New York: United Nations; London: H.M. Stationery Office, 1957.) 0.80 dollars; 5*s.* 6*d.*; 3.50 Swiss francs.

was recognized from the outset that the standard of the surveys from which it would be compiled varied greatly in different parts of the world, but it was felt that if the sheets were published in a uniform style and those features which had only been roughly explored were clearly distinguished, a very useful map would result. It was discussed at succeeding (4-yearly) conferences and by 1910 detailed specifications for projection, sheet lines, conventional signs and layer colouring had been drawn up, with the object of ensuring that sheets published by different countries should be as much a part of a uniform series as if they had been issued by the same publisher. By 1914 about a dozen sheets had been published. During the War several sheets were issued in styles closely approximating to that specified, but the Paris Conference of 1913 had ruled that sheets not completely conforming could not be regarded as part of the International Map, and in the first report of the Central Bureau of the Carte International du Monde (1921) two index diagrams were printed—one showing international sheets and the other sheets sufficiently similar to be conveniently used to supplement them. This distinction was confirmed by the conference of 1928 and firmly adhered to in the period between the Wars. Some of the most important contributions, including the American Geographical Society's series of sheets of Hispanic America, which was commenced in 1922 and completed in 1945, fall in the latter category, though they closely resemble International sheets.

In 1939 a map on this scale was again found to be most useful, and many sheets were prepared by military establishments. As time went on, they departed more and more from the specifications for the International Map and by the end of the War the position was very confused. In September 1953 the functions of the Central Bureau at Southampton were transferred to the United Nations Cartographic Office and an attempt was made to find out what had been published. The first result was an index diagram in World Cartography, Vol. 3. The report of the regional cartographic conference referred to above contains a reproduction of this diagram, which bears the date January 1957, though World Cartography, Vol. 4, which was published in the first half of 1956, and was devoted entirely to the International Map, contains a later diagram showing many more sheets, particularly in Asiatic Russia and Australia. It also contains most useful reproductions of the resolutions of 1913 and 1928.

The report for 1955 on the International Map of the World on the Millionth Scale (published in 1957) again shows more sheets, this time mostly of China. In both cases it is explained that the additional sheets are not necessarily newly published, but that their existence had not previously been reported to the United Nations. However, an inspection of the tabulated list of sheets reveals the fact that a great many, particularly of these additional sheets, are published by either the Geographical Section of the General Staff of Great Britain, or the Army Map Service of the United States, and are for "official use only, and not for sale or distribution". What is not revealed is the equally important fact that in general they depart considerably from the specifications for the International Map, though it is made clear that many of those of China are in black-and-white only and in the Chinese language. In fact, almost no reference is made to the distinction so carefully drawn in the years before 1939 between International and other sheets. Since the latter have become so very heterogeneous, some of them having little except projection and sheet lines in common with the International Map, the report is of little value as a guide to the present state of what used to be known as the Carte International du Monde. It would be a great pity if the challenging but very desirable and, one hopes, not unattainable objective of a homogeneous series of maps covering the whole world which for so long received the support of many distinguished geographers and surveyors should become obscured by a welter of second-rate publications, not all of which are even on public sale. A. M. FERRAR

INSECTS OF MICRONESIA

THE attention of students of the terrestrial Arthropoda in general is directed to a series of publications by the Bernice P. Bishop Museum, Honolulu, Hawaii, entitled "Insects of Micronesia". The geographical area covered includes practically all the oceanic islands of the north-western Pacific Ocean west of the 180th meridian and north of the equator. The chief island groups are the Marianas, Carolines, Marshalls and Gilberts, and the isolated islands are Ocean, Nauru, Wake, Marcus, the Bonins and the Volcano Islands. Altogether, Micronesia comprises some 2,400 islands under the administration of the United States, the United Kingdom and Australia. The former Japanese possessions, the Bonin Islands, Volcano Islands and Marcus, are now under United States mandate.

This series is based largely on the collections made between 1947 and 1953 by the Pacific Science Board (U.S. National Research Council) with the financial support of the U.S. Office of Naval Research, but much material was collected during the Second World War by American Service-men and previously by Japanese workers headed by Prof. Teiso Esaki, of the University of Kyushu. Since 1953 the work has been financed by the U.S. National Science Foundation, which has also assisted in the publication of the series.

"Insects of Micronesia" is planned to appear in twenty volumes which will be published at irregular intervals when ready. Vol. 1, which explains the scope and aims of the series as well as discussing the environment and natural history, was published in 1954 and is by Dr. J. Linsley Gressitt, entomologist at the Bishop Museum and leading spirit in this ambitious project. Vol. 2, published in 1955, is a comprehensive bibliography together with a subject index and is by Prof. Teiso Esaki, E. H. Bryan, jun., and J. L. Gressitt. Vol. 3 will be devoted to the Arachnida, Vol. 4 to the Crustacea, and Vols. 5–19 to the insect orders, followed by a summary in Vol. 20. Although none of these volumes has been completed, twenty-two parts have been issued to date.

This work is being undertaken by 115 specialist authors representing about fifty institutions in some thirteen countries, and is an example of the international effort required to deal with the vast assemblage of insects. Some idea can be gained of the increase in knowledge resulting from this publication by reference to the most recent issue, Vol. 7, No. 3, Heteroptera Aradidae, by Ryuichi Matsuda and Robert L. Usinger, in which the number of known species of this obscure family of fungus-feeding bugs is raised from thirteen to forty.

It is to be hoped that "Insects of Micronesia" will be successfully concluded in the not too distant future. W. E. China

A TRAP FOR INSECTS BITING SMALL VERTEBRATES

By Dr. W. H. R. LUMSDEN

East African Virus Research Institute, Entebbe, Uganda

In estimating the biting insect attack on man the bait may be made to perform the work of catching, as in the 24-hr. catch system with human catchers[1], and so confusing factors are minimized. In the case of other animals, however, a difficulty arises. If men are used for catching the insects alighting to feed on an animal bait, it remains in doubt whether the insects are primarily attracted to the animal or to the men, only biting the animal secondarily. Conversely, some of the insects biting the men might be expected to bite the animal if it was alone. Previous attempts to resolve this difficulty with unattended traps baited with animals have employed traps with restricted inlets[2,3]. Such traps are very successful for some species of mosquito, less so for others, perhaps because species vary widely in their readiness to enter. Further, these traps do not retain all the insects entering them; a certain, probably variable, proportion escapes[3]. The essentials of an improved design appeared to be that access to the bait should be as open as possible and that insects attracted to the bait, and captured, should not be able to escape afterwards. Some reconciliation of these apparently mutually exclusive characteristics has been accomplished in the trap to be described, which samples at regular intervals the flying insects in the vicinity of a bait which is as nearly as possible freely exposed.

A first design of trap[4] employed a horizontal flow of air over the bait. Although it was successful its efficiency was considered likely to vary with changes in wind direction and velocity, and so it has been superseded by a vertical design (Fig. 1). A 'Vent-Axia' 12-in. fan is mounted on a framework of iron strip and rod over the centre of a platform of hardboard. The trap is quite open around the platform for a height of 15 cm. Above this, and up to the base of the fan assembly, a conical space is partially enclosed by truncated sectorial pieces of transparent cellulose acetate sheet between the edges of which are spaces about a centimetre wide. The bait, in the middle of the platform, is thus visible from all directions above the horizon except from directly and nearly directly overhead, and access of insects to it is practically unimpeded. Above the fan a metal cylinder carries a wire gauze funnel which leads laterally to a small chamber fitted with a collecting bottle; the bottle contains a killing agent—potassium cyanide or pyrethrum.

The switching of the fan motor is performed by a 'Sunvic' hot-wire vacuum switch, using as a control an ordinary alarm clock the minute hand of which trails a piece of hair-spring over a surface of aluminium foil out of which are cut sectorial pieces to correspond with the desired 'off' periods.

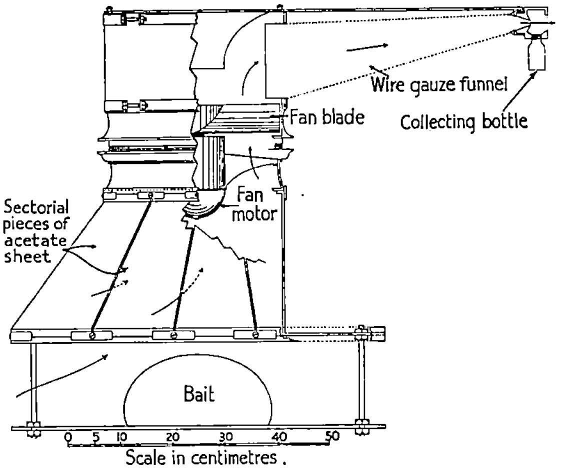

Fig. 1

Comparisons of the performance of the first design of trap on various cycles of operation—continuous running and 'on' and 'off' periods, respectively, and 2 and 3 min., 5 and 5 min., and 2 and 8 min.—led to the selection of 'on' 2½ and 'off' 5 min. periods giving eight complete cycles per hour. This cycle has been retained in the larger trap with, so far, no further experimentation. Other pilot studies with the first design of trap concerned the effect of different animal baits, the periodicity of activity and the effects of different environments and levels. All these studies gave promising results although the numbers caught were only moderate; for example, in sixteen nights at ground-level in the compound of the Institute, 940 mosquitoes were taken on four guinea pigs as bait—an average of 59 per night. The new design appears much more effective; under approximately similar conditions both with regard to trap operation and expected mosquito density the new design took 2,449 mosquitoes on one rabbit in five nights, an average of 490 mosquitoes per night.

Some first results to indicate the efficiency of the new design are as follows:

(*a*) The effect of the bait; 10 all-night runs, alternately with and without a grey rabbit; ground-level, East African Virus Research Institute compound (see Table 1).

The occurrence of small numbers of mosquitoes in the trap in the absence of bait is to be expected as the trap will catch mosquitoes entering it by chance at the appropriate time. However, in this particular case a cage which, fouled by the animal, may have some attractive power, was present in both series.

Table 1

Mosquito species	Arithmetic mean number of females caught per night	
	With rabbit	Without rabbit
Taeniorhynchus metallicus	1·0	0·6
fuscopennatus	475·8	57·6
africanus	9·0	2·0
uniformis	1·4	0·0
Culex spp. indet.	2·6	0·0
Total—mean	2,449—489·8	301—60·2

(*b*) The effect of position; 12 all-night runs, alternately at ground-level and 3 m. above it, in a tree; bait, one grey rabbit; East African Virus Research Institute compound (see Table 2).

Transference of the catching position into the tree is associated with a reduction in attack by some species and an increase by others.

Most of the mosquitoes caught are unfed and therefore may be assumed to be caught when exploring the bait preparatory to biting.

In conclusion, it may be pointed out that, besides the uses indicated above, the trap has possibilities for the investigation of the potency of attractants other than those emitted by the bodies of animals.

Table 2

Mosquito species	Arithmetic mean number of females caught per night	
	Ground	Tree
Uranotaenia sp.	0·0	0·2
Ficalbia plumosa	0·2	0·0
Taeniorhynchus metallicus	0·5	3·2
maculipennis	0·0	0·2
fuscopennatus	269·5	26·7
aurites gp.	0·7	4·7
africanus	10·8	0·0
uniformis	0·8	0·0
Aēdes africanus	0·2	0·2
Culex annulioris	0·0	0·2
spp. indet.	1·8	11·8
Total—mean	1,704—284·0	282—47·0

ELECTRON MOBILITY IN BIOLOGICAL SYSTEMS AND ITS RELATION TO CARCINOGENESIS

By DR. R. MASON

Department of Chemical Crystallography, University College, London, W.C.1

IN 1941, Szent-Györgyi[1] suggested that some biochemical processes could be better understood if protein molecules and extended systems of proteins were imagined to possess common energy bands similar to those which are derived from the collective-electron model of crystals; the conductivities of dyed protein films were later cited[2] as evidence for the usefulness of such an approach, although such limited data were scarcely conclusive. A good deal of other suggestive, but still not conclusive, evidence led Evans and Gergely[3] to examine theoretically the possibility of bands of energy-levels in proteins as a consequence of electronic conjugation through the π-orbitals in a protein structure represented by the scheme shown in Fig. 1.

These authors concluded that a banded structure was possible and indeed would actually confer a small extra stability on the system; their results, with nitrogen assumed to be trigonal planar (the most likely stereochemistry), are given in Table 1, which lists the range of energy bands in eV. relative to the lowest filled level, together with the electronic population of the bands.

Table 1. RANGE OF ENERGY BANDS (eV.)

Band 1	0·00–0·13	Doubly filled
Band 2	3·17–3·43	Doubly filled
Band 3	6·48–6·60	Unfilled

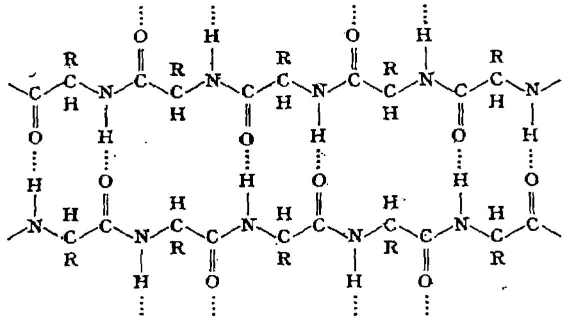

Fig. 1

Three main conclusions were discussed by Evans and Gergely: a protein structure is non-conducting in the ground-state and can assume conducting properties only on excitation; the width of the forbidden zone (∼ 3 eV.) is such that conduction can never be realized by thermal excitation, but can take place by the absorption of photons of suitable energy; finally, the narrowness of the bands, as compared with a metal or graphite structure, suggests "that in order to transfer electrons to or from empty or full levels of another system, the energy levels of the structures must be closely matched".

The calculations received, perhaps unexpectedly, excellent confirmation from the measurements of Eley *et al.*[4] of the semiconductivity of proteins. Plasma albumin, fibrinogen and edestin were shown to possess conducting properties which are consistent with a band structure having an energy gap of 2·1–2·6 eV. Later work[5] described dry hæmoglobin as having a semiconductivity with an energy gap of 2·7 eV., while separation into globin and hæm gave observed gaps of 3·0 and 1·8 eV., respectively; it was also suggested that while these experiments had been carried out on denatured proteins, similar results were indicated for natural hæmoglobin.

The importance of the conclusion reached by Evans and Gergely regarding the requirement for close matching of energy-levels if charge transfer is to

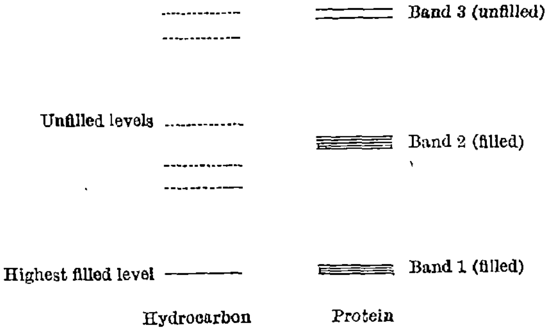

Fig. 2

take place can be discussed from the point of view of a molecular complex formed from a protein and an aromatic hydrocarbon (the latter is chosen because of the availability of data from quantum-mechanical methods concerning energy-levels, etc.). The conditions which must be satisfied in such a complex, if electrons are to be transferred from one molecule to the other, have been pointed out by various authors (see, for example, ref. 6), and may be written in the form

$$h\nu = I_D - E_A - \Delta$$

where $h\nu$ is the energy required to bring about charge transfer, I_D the ionization potential of the donor, E_A the electron affinity of the acceptor and Δ the stabilization of the ion pair. Let us assume that the electronic condition of the complex before any charge transfer takes place can be represented as in Fig. 2, that is, the highest filled level of the hydrocarbon coincides with the lowest filled band of the protein. This assumption, implying that

$$I_D \text{ (band 1)} = E_A + \Delta$$

cannot, unfortunately, be examined in any rigorous fashion so far as we know and its only justification is the results which follow its adoption. Our object—to alter the electron population of the highest filled band in the protein in such a way that conduction can take place—will now be achieved when an unfilled level of the hydrocarbon occurs with an energy which is within the energy range of the highest filled band in the protein, that is, when the energy separation between the highest filled and the *n*th unfilled level of the hydrocarbon

$$\Delta E_n = 3{\cdot}23 \pm 0{\cdot}19 \text{ eV}.$$

If this condition is fulfilled, the hydrocarbon may be regarded as 'active', and this activity, which therefore corresponds to the induction of electron mobility in the protein, will afterwards be considered to be an essential prerequisite in the process of carcinogenesis by these molecules.

Table 2 gives the energy difference between the highest filled and successive unfilled levels, in units of β (the resonance integral), as calculated by the simple molecular orbital method; these values have been calculated from the "Dictionary of Values of Molecular Constants"[7], and Prof. B. Pullman has generously provided energy-level schemes for a number of molecules which do not appear in those tables. The carcinogenic indices are taken, in most part, from Hartwell's[8] and Pullman's[9] surveys. 'Activity' can be seen to correspond approximately to the range

$$1{\cdot}10 \leqslant \Delta E_n \leqslant 1{\cdot}18$$

with the unit of energy on this scale, therefore, approximately 2·8 eV., a value in not unreasonable agreement with spectroscopic data. The relation suggests that the matching of energy-levels may be even more critical than is indicated by Evans and Gergely's calculated band-widths, but this must not, perhaps, be considered too seriously when the shortcomings of the theoretical method are remembered. It can also be seen from Table 2 that the molecules which satisfy this energy criterion possess, with the exception of 3,4-benzophenanthrene, one or more unfilled levels which lie below those coming into coincidence with the highest filled band in the protein; once electron mobility has been induced in the protein, these lower unfilled levels of the hydrocarbon must be imagined to act as further 'sinks' for electrons from the protein. The result of forming a complex of an 'active' hydrocarbon and a protein is therefore to induce positive-hole conduction in the hitherto completely-filled band and also to transfer electrons to a state of lower energy.

Of the 34 hydrocarbons tabulated, five are known, with some certainty, to be carcinogens of varying potency, namely, 3,4-benzophenanthrene, 1,2 : 5,6- and 1,2 : 7,8-dibenzanthracene, 3,4-benzpyrene and 3,4 : 8,9-dibenzopyrene, while 1,2-benzanthracene is now also thought to be active. All these molecules satisfy the stipulated criterion for ΔE_n, the remaining molecules falling outside the range with the exception of anthanthrene, which theory predicts should be active (very limited experimental results suggest that it is inactive), and 1,2 : 7,8-dibenzofluorene, which should be inactive but is found to be carcinogenic (although there appears to be some doubt here also). 1–12-benzoperylene and 2,3 : 6,7-dibenzofluorene come within the 'active' range but no data on their physiopathological properties are available.

Several molecules appear in Table 2 in which intramolecular overcrowding is known to exist; the

Table 2

Molecule	ΔE_1	ΔE_2	ΔE_3	ΔE_4	Activity

calculations of the energy-levels for these compounds can scarcely have any reliability placed upon them and this may account for the exception which 3,4-benzophenanthrene makes to the other carcinogens in not having an unfilled level below that level which coincides with the highest filled band in the protein.

When electrons from the highest filled band fall to lower unfilled levels in the hydrocarbon component of the complex, work (possibly in the form of some synthesis) may be done on the system, and Szent-Györgi's suggestions as to "why catabolic processes prevail over anabolic ones in damaged tissues (and cancer ?) . . ." are, perhaps, now more readily understood for the particular example of chemical carcinogenesis. It is therefore tempting to suggest that the relative potency of the carcinogen is related to the energy gap through which electrons from the highest filled band fall to reach unfilled levels in the hydrocarbon (and the data of Table 2 suggest that this may not be a completely misleading concept), but here again we must recognize the inadequacies of the theoretical methods and the present paucity of data.

The banded electronic model of a protein suggests, also, that radiation carcinogenesis may be interpreted as the result of electron promotion from the highest filled band to the conduction band proper of the protein. It follows that the overall result is one of inducing positive-hole conduction in the highest filled band and afterwards performing work on the system when the electrons promoted by photon absorption fall back to their ground state. If oxygen adsorption leads to impurity-levels close to the filled band, electron promotion will be facilitated and we may thus be able to understand the increase in radiation sensitivity, which malignant cells show on adsorption of oxygen, in this way.

The theory of the mechanism of chemical carcinogenesis which has been outlined here suggests experiments by which its usefulness may be judged. If induction of conducting properties in the protein is a necessary stage in carcinogenesis, such related effects as the diamagnetism and electrical conductivity of an 'active' complex should be quite different from the sum of the effects due to each component of the complex when they are not involved in charge-transfer processes. It is therefore hoped to extend recent crystallographic studies of carcinogen–purine complexes[10] to X-ray and diamagnetic investigations of complexes formed from carcinogens and nucleic acids or proteins, in addition to further theoretical consideration of these molecules.

Finally, it should be pointed out that the electronic structure of a protein ion in an active complex will be quite different from that usually assumed for protein ions in solution. In the latter case, the net charge is due to ionization in the side-chains of the protein, and it is unlikely that such perturbations can conjugate through these chains to the electronic system in which we have been interested.

These investigations are supported by a grant from the British Empire Cancer Campaign.

CONTRIBUTION OF DEOXYMETHYLPENTOSES TO THE SEROLOGICAL SPECIFICITY OF SOME BACTERIAL POLYSACCHARIDES, AND THE RECOGNITION OF A NEW SUGAR, PARATOSE

By Dr. D. A. L. DAVIES
Microbiological Research Establishment, Porton, Wilts

Dr A. M. STAUB
Institut Pasteur, Paris

AND

Dr. I. FROMME, Dr. O. LÜDERITZ and Prof. O. WESTPHAL
Dr. A. Wander Forschungsinstitut, Freiburg-Zähringen

TWO different deoxymethylpentoses have been found in specific polysaccharides extracted from various species of *Salmonella*, tyvelose in the products of group *D* strains (*S. typhosa*[1-3] and *S. enteritidis*[2]) and abequose in the products of group *B* strains (*S. abortus-equi*, *S. paratyphi B*[2-4] and *S. typhimurium*[4]). These sugars are very rapidly liberated from the polysaccharides on acid hydrolysis, which suggested that they might occupy terminal positions in the polymer chains and contribute to the specificity of groups *D* and *B*. Analyses of polysaccharides extracted from other species of *Salmonella* confirmed the presence of tyvelose in other group *D* strains and of abequose in other group *B* strains[5] (Table 1), but the presence of sugars having similar chromatographic behaviour to tyvelose and abequose was revealed in members of other groups (*S. paratyphi A* in group *A*; *S. Kottbus* and *S. newport* in group C_2)[5].

It has been shown that specific reactions of immune sera with homologous polysaccharides can be inhibited by single sugars[6]. In the *Salmonellae*, abequose inhibits the precipitation of an anti-*S. paratyphi B* serum by the homologous polysaccharide and tyvelose inhibits precipitation of an anti-*S. typhosa* serum by the homologous polysaccharide. Neither abequose nor ascarylose inhibits the latter system[7] although ascarylose, a deoxymethylpentose extracted from

Table 1. COMPOSITION OF THE SPECIFIC POLYSACCHARIDES OF GROUPS *A*, *B* AND *D* *Salmonellae*

Group	Species	'O' antigen (Kauffman–White)	Galactose	Glucose	Mannose	Rhamnose	Abequose	Paratose	Tyvelose
A	*S. paratyphi A*	1 2 12	+	+	+	+		+	
B	*S. paratyphi B*	1 4 5 12	+	+	+	+	+		
	S. typhimurium	1 4 5 12	+	+	+	+	+		
	S. abortus-equi	4 12	+	+	+	+	+		
	S. budapest	1 4 12	+	+	+	+	+		
	S. stanley	4 5 12	+	+	+	+	+		
	S. salinatis	4 12	+	+	+	+	+		
D	*S. typhosa*	9 12	+	+	+	+			+
	S. enteritidis	1 9 12	+	+	+	+			+
	S. gallinarum	1 9 12	+	+	+	+			+
	S. dar-es-salaam	1 9 12	+	+	+	+			+

Parascaris equorum, cannot be distinguished chromatographically from tyvelose[8]. These results indicated that tyvelose and abequose do contribute to the specificity of groups *D* and *B Salmonellae* and suggested that the specificities on which the Kauffman–White scheme is based are related, at least in part, to their content of the respective deoxymethylpentose. It could also be visualized that sugars present in the polysaccharides of *Salmonellae* of groups other than *D* and *B*, which could not be distinguished chromatographically from tyvelose and abequose, might in fact be isomers with closely similar properties. A re-examination of the composition of *S. paratyphi A* specific polysaccharide, previously reported to contain tyvelose, is recorded here, and the presence of a deoxymethylpentose has been established which is not tyvelose, nor is it identical with any sugar of this series previously recorded.

Cells of *S. paratyphi A* were extracted by the phenol/water method and the lipopolysaccharide component recovered in purified form by high-speed centrifugation[3]. After hydrolysis with *N* sulphuric acid, analysis on paper chromatograms, using authentic sugar samples for comparison, revealed the following sugars: galactose, glucose, mannose, rhamnose and a sugar which migrated faster than rhamnose and had an R_F value close to that of tyvelose. When hydrolysates of lipopolysaccharides obtained from *S. paratyphi A*, *S. typhosa* and *S. abortus-equi* were examined chromatographically side by side it became clear that the fast-running component of *S. paratyphi A* ('Paratose') was not identical either with tyvelose or abequose; the $R_{\text{rham.}}$ values were abequose 1·16, tyvelose 1·29 and paratose 1·25 (pyridine–butanol–water, 4 : 6 : 3). Like tyvelose and abequose, paratose is the first sugar to be released from its polysaccharide on acid hydrolysis. A sample of paratose was isolated by elution from paper chromatograms; it contains one oxidizable aldehyde group determinable quantitatively by the Willstätter–Schudel method. Oxidation with 1 mole of periodate produced, besides formic acid, a breakdown product which gave a strongly positive Webb reaction[9]; this is an intense red colour which develops on heating with *p*-nitrophenylhydrazine in trichloracetic acid, followed by the addition of strong alkali. The reaction is characteristic of 2-deoxysugars which have at least a C_6 straight chain; 2-deoxytetroses do not react[10]. A strongly positive reaction has also been obtained with the C_5 periodate breakdown products of tyvelose and abequose. It therefore seems probable that, like tyvelose and abequose, paratose belongs to the group of naturally occurring deoxymethylpentose sugars, recently characterized fully as 3.6-*bis*deoxy-aldohexoses[11].

From Table 1 it will be seen that galactose, glucose, mannose and rhamnose are present in all the *Salmonella* polysaccharides investigated, which include representatives of groups *A*, *B* and *D*. Group specificity, however, is clearly associated with the presence of paratose, abequose and tyvelose.

Although deoxymethylpentoses have been isolated thus far only from one group of bacteria (*Salmonellae*)[2,3] and from one animal source[8], it is clear that they are more widely distributed, at least among bacteria. In the 'O' antigens of some *Escherichia coli* strains (O 55 and O 111) deoxymethylpentoses have been found[3] which behave chromatographically like abequose; studies of their chemical identity and immunological role are in progress. In the *Pasteurellae*, smooth forms of *P. pseudotuberculosis* yield lipopolysaccharides containing a number of different sugars[12], and from each of the five serological groups[13] the lipopolysaccharide possesses a different specificity. In two instances (groups IV and V), one component could not be distinguished chromatographically from tyvelose; it is noteworthy that a serological cross-reaction has been recorded between *P. pseudotuberculosis* and *Salmonellae* of group *D* [14,15], the latter containing tyvelose. Hydrolysates of *P. pseudotuberculosis* group II lipopolysaccharide revealed on chromatographic analysis a sugar indistinguishable from abequose. Erythrocytes sensitized with the group II lipopolysaccharide can be agglutinated by *Salmonella* group *B* antisera, and erythrocytes sensitized with *Salmonella* group *B* lipopolysaccharide (for example, *S. salinatis*), which contain abequose, are agglutinated by *P. pseudotuberculosis* group II antisera.

In the remaining *P. pseudotuberculosis* groups (I and III) not all the sugars have been identified but fast running components appear to be present. However, in all instances isolation of the sugars will be necessary for a satisfactory identification.

HAPTOGLOBIN TYPES IN BRITISH, SPANISH BASQUE AND NIGERIAN AFRICAN POPULATIONS

By Dr. A. C. ALLISON*, Dr. B. S. BLUMBERG† and Mrs. ap REES

Department of Biochemistry, University of Oxford

SMITHIES[1,2] found that the patterns obtained by starch gel electrophoresis of sera from different human subjects fell into three groups. The determinant proteins combine with hæmoglobin and appear to be identical with the haptoglobins previously studied by Jayle and his colleagues[3,4]. It has therefore been suggested by Smithies and Walker[5] that the groups should be named haptoglobin types 1–1, 1–2 and 2–2 (formerly types I, *IIA* and *IIB*, respectively). Preliminary genetical analysis[6] indicated that the groups correspond to the three genotypes produced by a single pair of allelomorphic genes. In fact, our unpublished observations suggest that the genetical control of the haptoglobin types is more complex. A detailed discussion of the evidence will shortly be submitted for publication. In the meantime results can be expressed in the nomenclature of Smithies and Walker, with the addition of a fourth group of subjects in which no haptoglobin at all can be detected, for which the designation type O–O is suggested.

Table 1. Haptoglobin Types in Various Populations

Population	No. tested	0—0		1—1		1—2		2 2		Authors
		No.	(Per cent)	No.	(Per cent)	No.	(Per cent)	No.	(Per cent)	
Canadian	49	0	0	10	21·1	25	50·5	14	28·4	Smithies
American	54	0	0	6	11·1	29	53·7	19	35·2	Sutton *et al.*
British	218	6	2·7	22	10·1	121	55·5	69	31·7	Allison *et al.*
Basque	107	1	0·9	15	14·0	49	45·7	42	39·3	Allison *et al.*
Liberian and Ivory Coast (African)	142	0	0	69	48·7	60	42·3	13	9·1	Sutton *et al.*
Nigerian (African)	99	32	32·3	53	53·5	11	11·1	3	3·0	Allison *et al.*

The frequency of the haptoglobin types in different populations is of anthropological and genetical interest. It may also provide a clue to the way in which this remarkable polymorphism is maintained. The only published population studies of which we are aware are those of Smithies[2] on Canadians and of Sutton *et al.*[7] on Americans and on West Africans from Liberia and the Ivory Coast. In this article the results of haptoglobin type analyses of 218 British subjects, 107 Spanish Basques and 99 Nigerian Africans are presented.

The British sera were taken from unselected laboratory staff and blood donors in the Oxford region. The Basque bloods were collected as described elsewhere[8]. The African sera were taken from Yoruba of Ilobi, Western Nigeria.

Fresh oxyhæmoglobin was added to all sera to give a final concentration of the order of 100–120 mgm. per 100 ml. before electrophoresis in starch gels[2]. Each gel was then cut horizontally and one half stained with benzidine, as described by Allison and ap Rees[9]. The addition of enough hæmoglobin nearly to saturate the haptoglobins, but not much more nor less, and benzidine staining of the gels after electrophoresis, greatly facilitates the identification of the haptoglobin types, which may not otherwise be easy. As will be mentioned below, the discrepancy between our results and those of Sutton *et al.* on West Africans may be attributable to differences in technique.

The results of our three surveys, together with those of Smithies on Canadians and Sutton *et al.* on Americans and Africans from Liberia and the Ivory Coast, are summarized in Table 1. The frequencies of the various haptoglobin types in the British series are not significantly different from those in the small Canadian and American series, although the former includes six subjects of type O–O, none of which was described by Smithies or by Sutton *et al.* The frequencies in the Basque series also are not significantly different from those in the British, Canadian and American series. Thus the uniqueness of the Basques, shown in their low *B* and Fy^a and high *Rh*-negative frequencies[8,10], is not reflected in their haptoglobin types.

The haptoglobin frequencies of the Africans are, however, quite different. One-third of the Nigerian Africans lack haptoglobins altogether, and most of the remainder are of type 1–1. The discrepancy between these results and those of Sutton *et al.* may represent a difference between Africans from Nigeria on one hand and from Liberia and the Ivory Coast on the other; but it is probably attributable to the inclusion by Sutton *et al.* of a number of subjects of group O–O in their group 1–1. The distinction between these two groups is difficult without specific staining of hæmoglobin.

The high frequency of Nigerians without haptoglobins raises a physiological point. It has been shown that the 'renal threshold' for hæmoglobin is due to binding of the pigment by haptoglobins in the serum[9,11]. In subjects without haptoglobins most hæmoglobin liberated into the blood stream passes into the urine. Since hæmoglobinaemia must frequently occur after malarial attacks as well as after vigorous exercise[9], it might be expected that some degree of hæmoglobinuria and loss of iron in the urine would be common among Africans. To our knowledge, this point has not been investigated.

† Fellow of the Arthritis and Rheumatism Foundation.

The fact that several haptoglobin types exist side by side in a number of different populations indicates that it is a true polymorphism. This may have been maintained, like those of the blood groups and abnormal hæmoglobins, by a balance of selective forces related to susceptibility to disease[12]. The absence of haptoglobins might be disadvantageous, particularly in regions where there is a deficiency of iron in the diet. The fact that so many Nigerians lack haptoglobins is presumably due to a compensatory advantage in persons heterozygous for the factor concerned. The low frequency of type 2–2 in the tropics suggests that it may confer protection against one or more conditions common in temperate, but not in tropical, climates.

Dr. F. Alberdi kindly co-operated in the collection of the Basque blood specimens and Drs. Jean Grant and H. Preston in the collection of British bloods. The Nigerian specimens were collected by one of us (B. S. B.) as part of the work carried out on an expedition supported by the Wenner Gren Foundation, Inc., and grant No. *H*-3161 from the National Heart Institute, U.S. Public Health Service. The help of Prof. B. G. T. Elmes, Ibadan, is gratefully acknowledged.

ONE-ELECTRON *VERSUS* TWO-ELECTRON TRANSFER PROCESSES IN THE MECHANISM OF OXIDATION-REDUCTION REACTIONS IN SOLUTION

By Prof. JOSEPH WEISS
University of Durham, King's College, Newcastle upon Tyne

IN recent years there has been some discussion regarding the question of one-electron *versus* two-electron transfer processes in the mechanism of oxidation-reduction processes in solution. The concept of one-electron transfer processes, in its general form, was first put forward by Haber[1], and it has been confirmed by a large body of experimental evidence. The assumption of single electron transfer also leads directly to free radical intermediates which play such an important part in the mechanism of chemical reactions.

One-electron transfer processes also constitute an essential step in many photochemical (ref. 2*a*) and photosensitized reactions (ref. 2*b*) in solution. Moreover, it has been suggested that the formation of many of the so-called 'molecular complexes' is also due essentially to an electron transfer between the two components (ref. 2*c*).

In general, it is to be expected that one-electron transfer processes should predominate over two-electron transfers, as the latter are only likely to occur when there is a strong coupling between the electrons.

Although it is now generally accepted that in the majority of cases one deals with one-electron transfer processes, it is believed that there are certain oxidation reactions where two-electron transfer predominates[3]. In the latter cases, this assumption is mainly derived from the apparent inability to detect free radicals, and from the appearance of oxygen from the oxidizing reagent in the molecule which has been oxidized (as demonstrated by means of compounds labelled with oxygen-18).

In the following, an attempt has been made to show that all the relevant experimental facts are fully compatible with, and can be easily explained by, one-electron transfer processes.

From the theory of electron-transfer processes it follows (ref. 4*a*, *b*) that one of the significant features is that electron transfer leads to a more or less strongly bound primary (ionic) complex between the reacting partners; thus, in the case of two uncharged reactants: $A + B \rightarrow (A^{+}.B^{-})$. In general, the energy of interaction gained in the formation of the primary complex also makes an important contribution towards the 'driving force' of the electron transfer. The ionic complexes primarily formed will have a certain minimum life-time. An estimate of the probable life-time of such a complex in solution can be obtained from the time which is required for the water dipoles to interact with an ionic complex; this cannot be less than the time of relaxation of water dipoles in liquid water, which is of the order of 10^{-10}–10^{-11} sec. This will, however, only be a lower limit, because in the interaction of water molecules with an ion, the time of relaxation in the immediate neighbourhood of the ion will have to be considered. According to the work of Kozyrev[5] and others, these relaxation times can be considerably greater than those measured for the pure solvent and in certain cases they can be as long as 10^{-7} sec.

This may have the consequences, first, that the primary complex could be long lived enough to react as a separate entity with another reactant present in the solution, and secondly that the possibility of intramolecular changes within the complex must be taken into account. This follows from the consideration that the jump frequency for atoms (or ions) is given by $\nu = \nu_0 \exp(-E/kT)$, where E is the activation energy and ν_0 (frequency coefficient) is of the order of 10^{13}–10^{14} sec.$^{-1}$ for a typical atom (or ion) transfer. Moreover, such changes should have a negligible or only a very small energy of activation, as both the reacting species have free-radical character.

Thus, for example, even in a primary complex of the relatively short life-time of 10^{-10} sec., about $10^{-10} \times 10^{14} = 10^{4}$ jumps can take place if the process goes without appreciable energy of activation, and even up to activation energies of about 4 kcal. there would still be a high probability for an intramolecular transfer of a heavy particle; in the case of longer lived intermediates the situation is, of course, more favourable.

There is, therefore, a considerable probability that, during the life-time of the primary complex, intramolecular transfer of atoms or radicals will take place without any appreciable participation of the solvent.

A case where the primary complex is probably long lived enough to react with another molecule is found in the oxidation of ferrous ions by oxygen in acid solution[6], where presumably the primarily formed electron transfer complex, namely, $Fe^{2}+ + O_2 \rightarrow (Fe^{3}+ . O_2^{-})$, reacts with another ferrous ion giving $[Fe^{3}+ . O_2^{-} . Fe^{2}+]$, and this dinuclear complex then breaks up to give ferric ions and hydrogen peroxide. Additional support for this type of intermediate comes from the autoxidation of cobaltous amine ions where complexes of the structure $[Co^{3}+(NH_3)_5 . O_2^{2-} . Co^{3}+(NH_3)_5]^{4}+$ have actually been isolated.

Examples of supposedly two-electron transfer processes which can be explained on the basis of one-electron transfers are the following.

The reaction between hydrogen peroxide and iodide ions (ref. 7*a*). The first step is expected to be electron transfer according to the reaction

$$I^{-} + H_2O_2 \rightarrow (I . H_2O_2^{-}) \tag{1a}$$

followed by association of the iodine atom and OH radical within the primary complex:

$$(I . H_2O_2^{-}) \rightarrow I . OH + OH^{-} \tag{1b}$$

Oxidation of sulphite by chlorate. From the kinetics of this reaction it follows that the first step is a reaction between chlorate ion and sulphurous acid, and it has been shown by means of chlorate labelled with oxygen-18 that transfer of (about 2·3) oxygen atoms from the chlorate to the sulphite takes place (ref. 7*b*). On the basis of the theory given above, this reaction can be represented as follows:

$$ClO_3^{-} + SO_2 \rightarrow (ClO_3^{2-} . SO_2+) \tag{2a}$$

$$(ClO_3^{2-} . SO_2+) \rightarrow (ClO_2^{-} . SO_3) \tag{2b}$$

$$(ClO_2^{-} . SO_3) \xrightarrow{H_2O} ClO_2^{-} + H_2SO_4 \tag{2c}$$

with the corresponding reactions between the intermediately formed ClO_2^{-} and ClO^{-} (or HClO) with SO_2. Thus, one has single electron transfer processes followed by O^{-} transfers within the complex, possibly with some solvent interaction in the last stage.

Oxidation of sulphite by hydrogen peroxide (ref. 7*b*). This is a particularly interesting case because one now has an explanation of a hitherto unexplained fact that, whereas in the oxidation of sulphurous acid in acid solution two oxygen atoms from the hydrogen peroxide are transferred, in alkaline solutions, only one of the oxygen atoms of the hydrogen peroxide appears in the resulting sulphate[8]. According to the theory outlined here the reactions can be formulated as:

In acid solution:

$$H_2O_2 + SO_2 \rightarrow (H_2O_2^{-} . SO_2+) \tag{3a}$$

$$(H_2O_2^{-} . SO_2+) \rightarrow (HO . SO_3H) \tag{3b}$$

At higher pH:

$$H_2O_2 + HSO_3^{-} \rightarrow (H_2O_2^{-} . HSO_3) \tag{3c}$$

$$(H_2O_2^{-} . HSO_3) \rightarrow HO.SO_3H + OH^{-} \tag{3d}$$

Thus, in acid solutions, an OH^{-} and an OH radical may be transferred within the primary ionic complex, whereas the radical ions (HSO_3 or SO_3^{-}) formed from the sulphite anions should only associate with the OH radical but not with the OH^{-}.

Biological oxidation-reduction processes. The interesting results of Vennesland and Westheimer[9] concerning the reaction between deuterated ethanol ($CH_3.CD_2OH$) and diphosphopyridine nucleotide, catalysed by alcohol dehydrogenase, are fully in agreement with the general theory given above. (Proviso must be made here, of course, with regard to any possible role of the enzyme in the actual reaction mechanism which is, as yet, unknown.) If the reaction is assumed to take place directly between the two reactants, it could be represented by a one-electron transfer followed by a deuterium (or hydrogen) atom transfer, within the primary complex, from the alcohol radical ion to the monovalently reduced nucleotide. In the cases of hydrogen or deuterium atom transfer, there would also be an increased probability of transfer by a tunnel effect. As all such processes would take place during the life-time of the primary complex, it is not at all surprising that they proceed without hydrogen exchange with the solvent, as found experimentally.

Formation of free radicals. It is known that in the majority of oxidation-reduction processes free radicals do, in fact, appear as more or less stable intermediates. The occurrence of these can often be predicted on plausible physical grounds. For example, in the reaction (ref. 1*b*)

$$Fe^{2}+ + H_2O_2 \rightarrow (Fe^{3}+ . H_2O_2^{-})$$

the primary complex would be expected to break up by interaction with the solvent according to the equation

$$(Fe^{3}+ . H_2O_2^{-}) \rightarrow Fe^{3}+OH^{-} . aq + OH$$

giving OH radicals. Similarly, in the reaction between oxalate ions ($C_2O_4^{2-}$) and iodine atoms, the primary complex should break up to give the radical ion $C_2O_4^{-}$ thus

$$(C_2O_4^{-}. I^{-}) \rightarrow C_2O_4^{-} . aq + I^{-}$$

One may conclude, therefore, that in general the appearance of a free radical as a reacting entity depends on the intrinsic behaviour of the primarily formed one-electron transfer complex. This complex may release into the medium either a free radical or a valence-saturated species[10], the latter arising from a rearrangement within the complex prior to its break-up by the solvent (water).

INDUCED GENE UNSTABILIZATION

By Prof. STEPHEN ZAMENHOF, Miss ROSALIE de GIOVANNI and Dr. SHELDON GREER

Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York 32

A GENE may acquire a hereditary high mutability-rate either by its own mutation to an unstable form or as a result of the influence of another gene (which in turn is changed by a mutation or is introduced *de novo* into the genome). Whatever the cause, the resulting gene unstabilization might be of importance for evolution.

In this report, the observable phenomenon of unstability rather than the precise mechanism will be discussed. The experiments were performed on strains of *Escherichia coli* which have not been reported to recombine sexually; therefore, it is assumed that in this case the unstabilization is caused solely by a mutation (and not *de novo* introduction of another gene). In such strains, the site of the mutation (nuclear or cytoplasmic) cannot be unequivocally established; however, in the cases of induced unstabilization studied here, the effects were a result of the known interference with the structure of deoxyribonucleic acid molecules, and this points to this acid as the site of these changes.

The 'unstable gene' will be arbitrarily designated as the one with a spontaneous mutation-rate higher than 1 per 1,000 cells per generation. Studies of such high mutabilities were avoided in the past, partially because of the lack of proper techniques.

The cells of *Escherichia coli* can replace up to half the thymine in their deoxyribonucleic acid[1-3] by 5-bromouracil without losing the ability for subsequent division[4]. This replacement is reversible[5]. It occurred to us[4] that such a drastic (though temporary) change in the structure of deoxyribonucleic acid, which is believed to be the hereditary determinant[6], may result in a change in genotype: the recent findings that the replacement can occur without apparent cell division[3,5] and that the precursor is a nucleotide[7] (which may imply breakages in the sugar–phosphate chain of deoxyribonucleic acid) suggest the possibilities of faults during the replication of deoxyribonucleic acid even though 5-bromouracil afterwards disappears from the acid upon cultivation on normal medium.

We have reported that the spontaneous mutation-rate of strain *I* to the 5-bromouracil resistant strain *I/Br* was not changed by the introduction (and subsequent removal) of 5-bromouracil into and from deoxyribonucleic acid[4]. We now find that the spontaneous and ultra-violet-induced mutation-rates (both to prototrophy and to auxotrophy) of eight different markers in four different strains, tested in various media, with various concentrations of 5-bromouracil, and with and without intermediate cultivation, were also not changed. (Purine − mutant of strain *W*: mutation to purine +. Strain *I*: mutation to thymine +, streptomycin resistance, total auxotroph count. Strain A.T.C.C. 11887: mutation to lactose −. Uracil − mutant of strain A.T.C.C. 11887: mutation to uracil +, lactose +, total auxotroph count.) It must be concluded that the introduction (and subsequent removal) of 5-bromouracil to (and from) deoxyribonucleic acid is not a process that unstabilizes all the genes. It was of interest to study whether some genes can be unstabilized by such a process.

In a previous publication[4] we have reported that during the experiments on introduction of 5-bromouracil into deoxyribonucleic acid there appear 'pinpoint' or small colonies: because of their eventual disappearance after 140 generations we were not sure that they could be classified as typical mutations.

These changes have now been studied in more detail. The materials and the methods used were those described previously[1,3,4].

(1) *The nature of the changes.* It appears now that most of these changes to pinpoint colonies are typical mutations, with a varying degree of stability, that is, varying mutation-rate back to large colonies. For convenience in explaining experimental results, these mutations can be divided into three classes:

A. Typical mutations to stable 'pinpoints'. The back mutation of the latter has never been observed. The mutant 'pinpoint' strains can be maintained indefinitely by transferring from nutrient broth or nutrient agar as infrequently as every 24 hr.

B. Typical mutation to unstable 'pinpoint'. The latter back-mutate to normals which have a strong selective advantage over the 'pinpoint'; thus, any repeated transfer may eventually result in loss of the 'pinpoint' strain. It was found that the transfer of 14-hr. old (37°) pinpoint colonies containing approximately 10^6 cells still allows for the indefinite maintenance (tested for 150 generations or seven transfers) of the 'pinpoint' strain, thus proving that one deals here with a typical mutation.

We now find that 'pinpoints' of similar behaviour occur also in the spontaneously unstable Harvard strain[8] (A.T.C.C. 11887).

C. Change to 'pinpoints' so unstable that any attempt to transfer, even as early as 12 hr., results in a loss of the pinpoint 'strain'. This 'strain' may still be a typical mutant with an exceptionally high mutation-rate back to normal. If the back-'mutation'-rate approaches 1 per cell per generation, the change will usually be called a non-hereditary phenotypical change; perhaps there is no sharp dividing line between the two types of change.

The present techniques do not permit one to determine whether in each of these cases the descendants of a single cell all have only one single mutation-rate or a *whole range* of mutation-rates.

(2) *The mutation-rates.* After having established that the changes, at least in cases *A* and *B*, are hereditary, it seemed of interest to determine the rate of their occurrence (mutation-rate). The results are given in Table 1. In most cases only the lower or the higher limits of mutation-rates can be estimated from the mumber of colonies because of the selective advantage of the normal over the 'pinpoints'. As can be seen from Table 1, some mutation-rates for types *A* and *B* are higher than 3 per cent.

The highly unstable strain *I/Br* is of interest. Fifteen single large colonies of this strain were tested and *all* were found to produce 'pinpoints'. To ascertain that the change was indeed hereditary, three large colonies were carried through seven transfers

Table 1. MUTATION-RATES

Parent strain*	I			I'	I/Br
Unstabilizing or mutagenic agent*	5-bromouracil ?	5-bromouracil deoxyriboside		5-bromouracil	none
Type of mutant*	I/Br	A_1–A_3	B_1	A_4	B_2
Forward mutation-rate, per cell per generation†	4×10^{-10}	$> 10^{-3}$	$> 5 \times 10^{-3}$	$> 3 \times 10^{-3}$	$> 3 \times 10^{-2}$
Back mutation-rate, per cell per generation†		$< 5 \times 10^{-5}$	1×10^{-2}‡	$< 5 \times 10^{-5}$	

* See text; the subscripts denote different mutants.

† Where the actual mutation-rate cannot be determined, the upper or the lower limits were calculated from the frequency of mutants.

‡ Determined by early restreaking.

(180 generations); after these transfers, the cells still showed unchanged unstability.

(3) *Gene unstabilization.* It appeared first of interest to study the origin of gene unstabilization in strain I/Br. This strain was isolated as a mutant of strain I grown on medium containing 5-bromouracil in the conditions of incorporation of this analogue into deoxyribonucleic acid[4]. Two other 5-bromouracil resistant mutants isolated under similar conditions proved to be as unstable as strain I/Br. On mutation back to 5-bromouracil sensitivity (strain I'), the unstability is lost. Thus, the feature of gene unstability seems to be linked with the gene for resistance to 5-bromouracil. The nature of this linkage is not clear. To date we have not succeeded in isolating a I/Br strain without contact with 5-bromouracil; it is therefore not known whether this gene unstabilization is a result of incorporation of 5-bromouracil into deoxyribonucleic acid (see below) or merely a selection of a spontaneous unstable mutant I/Br. That this latter mechanism may be operative is indicated by the fact that the mutation-rate to I/Br (and therefore unstability) is not increased by the presence of 5-bromouracil[4]. It is of interest that the 2-thiothymine resistant strain I/TT[4], which exhibits cross-resistance to 5-bromouracil, is also as unstable as I/Br. This strain was isolated in the presence of 2-thiothymine, which is not incorporated into deoxyribonucleic acid, but increases the content of 6-methylaminopurine in deoxyribonucleic acid (see below).

In contrast to the above, the unstabilization in strain I could be demonstrated only in the conditions of incorporation of 5-bromouracil into deoxyribonucleic acid (Table 1). In recent years, hypotheses have been put forward that the only action of a mutagen is gene unstabilization and that the actual mutation of such an unstabilized gene may occur automatically at some later time, without the action of a mutagen[9]. If this be applied to the case under study, one may contend that 5-bromouracil acting on strain I produces unstable genes at a very high rate, recognizable by the subsequent high mutation-rate (types A and B). In the mutation of type A, this high mutability is lost at mutation; this situation occurs often in unstable genes. On the other hand, in the mutation of type B (B_1), the high mutability (high back mutation-rate) persists indefinitely (tested for at least seven transfers or 150 generations). This represents, therefore, a case of induced permanent gene unstabilization.

(4) *The inducing agents.* As mentioned above, the mutations occur spontaneously in unstable strains I/Br and I/TT. It appears that the stable strains I and I' can produce frequent mutants or become unstabilized or both, under the influence of agents (Table 1) which interfere with the structure of deoxyribonucleic acid.

A. Replacement of thymine by 5-bromouracil. The 'pinpoints' (I_8 and I'_8, respectively) of type A and B can be obtained in strain I and I' (back mutant of I/Br to 5-bromouracil sensitivity) when grown in broth containing 100 μgm. 5-bromouracil per ml. or 125 μgm. 5-bromouracil deoxyriboside[1] per ml., and then streaked on nutrient agar. No stable 'pinpoint' colonies were observed among 5,000 colonies (strain I') or 50,000 colonies (strain I) when 5-bromouracil or 5-bromouracil deoxyriboside was omitted.

It is of interest to note that a striking increase of mutation-rates in bacteriophage in the conditions of incorporation of 5-bromouracil into phage deoxyribonucleic acid has also been reported[10].

B. Replacement of thymine by 6-methylaminopurine[11]. This condition has been induced by growing the thymine-requiring strain I in basal broth containing a limited amount of thymine[1] (0·2–1 μgm. per ml.) or containing inhibiting amounts of 2-thiothymine (50 μgm. per ml.) and then streaking as usual on nutrient agar. It must be added that while 5-bromouracil produced stable (type A) and unstable (type B) 'pinpoints', the 2-thiothymine, which is not incorporated into deoxyribonucleic acid, produced only unstable 'pinpoints' (types B and C); the conditions of limited thymine produced only unstable 'pinpoints' of type C which cannot be as yet proved to be a typical mutation.

Two interesting cases of increase (up to 100-fold) in the spontaneous mutation-rate (to histidine independence or to streptomycin resistance) under conditions of thymine deficiency have been reported recently[12,13]; in both cases, however, the increased mutant frequencies ($2 \cdot 5 \times 10^{-6}$ or $2 \cdot 5 \times 10^{-9}$) still remained low.

The 6-methylaminopurine content has been reported to increase from 2 per cent (of thymine) up to 30 per cent, under conditions where an analogue inhibits the synthesis of deoxyribonucleic acid, but is not incorporated into it[11]. It was of interest to study whether this content increases also under conditions where the inhibitory analogue is incorporated into deoxyribonucleic acid, as in the case of 5-bromouracil. A preparation of deoxyribonucleic acid containing 42 per cent of 5-bromouracil (as referred to thymine) and a control preparation of the acid containing no 5-bromouracil were isolated and analysed as described previously[3]. The content of 6-methylaminopurine in the acid containing 5-bromouracil was not significantly higher (2·7 per cent) than that of control acid (2·0 per cent). It is concluded that when the cell can partially counteract the inhibition by building the analogue into deoxyribonucleic acid, it may do so in preference to increasing the content of 6-methylaminopurine, especially if there is no lack of thymine or thymidine (enriched nutrient broth). Thus, the genetic phenomena observed here when growing cells on 5-bromouracil seem to be due to the effect of this compound rather than to 6-methylaminopurine.

(5) *The nature of 'pinpoint' colonies.* The occasional appearance of hereditary 'G type', 'small' or 'pin-

point' colonies in many bacterial species has been frequently reported in the past. Such colonies occurred spontaneously or as a result of treatment with agents such as barium chloride, lithium chloride, Cu++, dyes, antibiotics or just ageing. In a few recent reports where a genetic analysis was made[14,15], it was found that the 'small' mutants were present in natural populations in proportions of the order of one cell per 50,000, but were selected for by the particular agent used and therefore appeared in high proportion after treatment with this agent. However, it would be premature to say that this is true of all the agents used, that is, that indeed none of them is a mutagenic agent.

The present study was thus far made primarily with strains *I* and *I'* and their stable 'pinpoint' mutants (type *A*): the unstable pinpoints (types *B* and *C*) are difficult to study because of the high mutation-rate to 'large'.

In the case of strains *I/Br* and *I/TT* the mutation to 'pinpoint' colonies is spontaneous and therefore no selective agent is involved; on the other hand, in the case of 'pinpoint' colonies produced in strain *I'* and *I* by the action of 5-bromouracil and 5-bromouracil deoxyriboside, it was first important to ascertain that the appearance of a high proportion of 'pinpoint' colonies is not due to selection by these agents. This was indicated by the 'reconstruction experiments' in which mixtures of 'pinpoint' and normal cells (containing approximately equal proportions of each) were used as inocula. In the case of strain *I'*, the cells were allowed to multiply 10^5-fold in the presence of 100 μgm. of 5-bromouracil per ml. After 24 hr., the proportion of 'pinpoints' decreased to 3 per cent, which is of the same order of magnitude as the proportion obtained by the action of 5-bromouracil itself when no 'pinpoints' were in the inoculum. In strain *I*, the cells were grown 24 hr. in unmodified enriched medium whereupon a 4-fold volume of fresh medium containing 200 μgm. of 5-bromouracil deoxyriboside per ml. was added and the incubation continued for another 24 hr. Under these conditions, there was merely a 2-fold increase in the number of cells; this, as checked by a 'reconstruction experiment', did not change the proportion of added 'pinpoints'. Both experiments (strain *I* and *I'*) were also repeated with the 'pinpoint'-free inocula, and in this case the 'pinpoints' appeared as mentioned before.

These results indicate that in both strains the appearance of 'pinpoints' is a result of the mutagenic or unstabilizing action of 5-bromouracil or 5-bromouracil deoxyriboside and not selection.

By direct observation of dividing cells on nutrient agar and by actual cell counts in nutrient broth it was found that the lag period of stable 'pinpoint' cells (from strain *I'*) was not longer than 2 hr.; the main factor responsible for the smaller size of the colony was the 1·4 times longer division time during the logarithmic growth.

A preliminary study of the nature of the difference between the two types of cells has been made. In the case of yeast, the thorough study of Ephrussi *et al.*[16] revealed that his "petit" mutants are deficient in certain respiratory enzymes. In our case, the study of the stable 'pinpoint' mutants from strains *I* and *I'* of *E. coli* revealed that it is unlikely that the mutation is of the respiratory nature: contrary to the results of Ephrussi *et al.*, the growth of the 'pinpoint' mutants of *E. coli* is just as depressed by the lack of oxygen (Brewer's agar under anaerobic conditions) as is the growth of the normal strain. It occurred to us that the poor growth of these mutants on regular nutrient agar ('Difco') may signify that they represent various complete or partial auxotrophs for substances present in this medium in sub-optimal quantities. That various types, rather than one type, of auxotroph occur can be expected if the inducing agent (5-bromouracil) enters a variety of molecules of deoxyribonucleic acid. As mentioned above, an unstable 'Harvard' strain studied by Goldstein and Smoot[8], which is known to produce a high proportion of mixed auxotrophs, also forms a high proportion of colonies of smaller size on nutrient agar. When our 'pinpoint' mutants from strain *I'* were tested in several media, the results obtained (Table 2) indeed clearly indicated that, at least in this case, we are dealing with a nutritional mutant having perhaps multiple and/or partial growth requirements. The required additional nutrients seem to be present in yeast supplement *A* ('Difco') and are partially destroyed by boiling (½ hr.). In tryptone–peptone–yeast extract ('Difco') strain *I'* cannot be distinguished from normal.

Table 2. STUDY OF ADDITIONAL GROWTH REQUIREMENTS OF THE STABLE 'PINPOINT' MUTANT I'_s AS COMPARED WITH ITS PARENT STRAIN I'

Strain			I'	I'_s

Remanent Magnetism of the Rajmahal Traps of North-Eastern India

Following a palæomagnetic survey of the Deccan Traps of India[1-3], we have extended our investigations of Indian rock formation to other geological ages. In particular we have made rock magnetic measurements on samples of lavas from the Rajmahal Traps of eastern Bihar. These lavas, which consist mainly of basaltic and pitchstone trap flows, overlie the Upper Gondwana shales and sandstones. They are most probably Jurassic in age, and according to Hobson[4] they represent the earliest part of the volcanic activity that afterwards, during the late Cretaceous and early Eocene periods, gave rise to the Deccan Traps.

During January 1957 we collected samples of the rocks from five localities spaced about 20 miles apart. Approximately ten samples were taken from each site, usually over a distance of several hundred yards. In two of the localities the material was found in the beds of streams, while in the remaining three the blocks were obtained from freshly exposed rock in quarries. The samples were analysed in Bombay and London.

The specimens taken from the three quarries (33 blocks in all) were found to be consistently magnetized along an axis directed towards the west of north with a steep upward dip. A total of 16 blocks from the two stream beds, on the other hand, were badly weathered and showed widely scattered directions of magnetization, and the results for these particular samples have been rejected.

The magnetic direction for the samples from the quarry sites are plotted in Fig. 1 and details of the measurements are given in Table 1. The steep upward dip (−64°) is consistent with the assumption that the Indian land mass occupied a position south of the equator at the time when the rocks acquired their magnetization, and if the mean direction of magnetization is taken to correspond to that of a geomagnetic axial dipole field at the time when the rocks were formed, we must suppose that the Rajmahal area had a southern latitude of 46° at that time. The corresponding ancient position of the north geographical pole, computed on the polar wandering hypothesis, lies in the southern Carribbean at lat. 13° N., long. 70° W., as shown by point IX in Fig. 2.

It is interesting to compare this result with those published previously[1-3,6] for the lavas of the Deccan Trap series. The north pole positions obtained from measurements made on rocks from eight different sites in the Deccan formation are also shown in Fig. 2. They fall into three categories :

(1) Sites V–VIII, which belong to the Lower Traps, give pole positions farthest to the south. The rocks are all reversely magnetized (that is, in south-easterly directions) with rather steep downward dips.

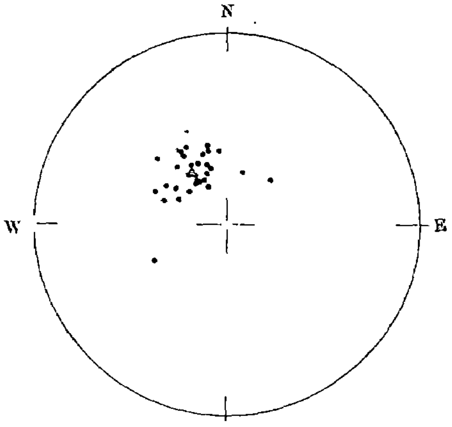

Fig. 1. Rajmahal area : ●, upward dips. Equal area projection

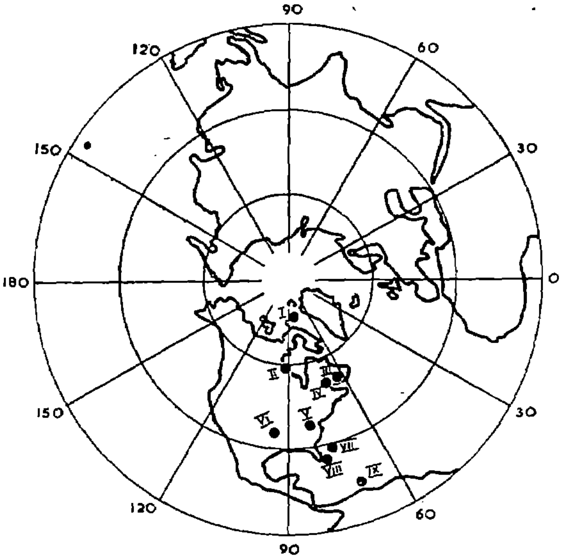

Fig. 2. Ancient pole positions for various sites : I, Pavagadh (upper) ; II, Pavagadh (lower) ; III, Amba (upper) ; IV, Nipani (upper) ; V, Linga ; VI, Nipani (lower) ; VII, Amba (lower) ; VIII, Khandala ; IX, Rajmahal

(2) Sites II–IV are all close to the tops of the Western Ghats, and give pole positions closer to the present geographical pole. The samples from these sites have normal magnetization (that is, towards the west of north), with considerably shallower upward dips.

(3) Site I is close to the top of Mount Pavagadh, and the rocks are acid tuffs believed to be more recent than the lavas of the main Trap sequence. Again the magnetic directions are normal, but the dips are almost zero.

It has been pointed out that this continuous decrease of dip with altitude above sea-level may be due to any one of three causes, namely :

(*a*) It may have occurred as a result of some mechanical effect associated with different depths of burial, such as that described by Graham[7].

Table 1. Rajmahal Rocks

Mean latitude of area	Mean longitude of area	No. of blocks	Mean intensity (c.g.s.u.)	Mean azimuth	Mean dip	Radius of 50 per cent circle of confidence*
25° 0′ N.	87° 51′ E.	33	$8{\cdot}85 \times 10^{-3}$	N. 328° E.	− 64° up	2°

* Measured by Fisher's method (ref. 5)

(*b*) It may be indicative of partial magnetic instability which would cause a pulling of the magnetic directions towards that of the present Earth's field. This would tend to increase the magnetic dips of the reversely magnetized rocks (1) and to decrease those of the normally polarized ones (2) and (3).

(*c*) It may represent a continuous northward movement of India relative to the equator during the time when the Deccan Traps were being erupted.

The Rajmahal lavas discussed in this communication are older than the Deccan Traps. They have steeper magnetic dips, and give a pole position (IX) farther from the present pole than any of the Deccan rocks. Considering this steeper dip in relation to postulates (*a*), (*b*) and (*c*) above, it appears that: (*a*) it is unlikely to have been caused by compressional forces associated with deep burial, since all the specimens collected came from the uppermost 250 ft. of the Rajmahal series, and it is improbable that they have ever been overlain by any substantial thickness of material[4]; (*b*) it cannot have been increased by magnetic instability in the present Earth's field, as the Rajmahal rocks are normally magnetized, and this effect would tend to reduce rather than to increase their magnetic dips.

It seems, therefore, that the combined results for the Rajmahal and Deccan Traps conform best with the postulate (*c*) and are compatible with the supposition that there was a continuous northward drift of the Indian land mass extending from the Jurassic to the Eocene.

This conclusion must be regarded as tentative pending a more detailed survey of the areas concerned. The work is continuing, and a full account will be given elsewhere.

The Triple Point of Argon as a Thermometric Fixed Point

IN connexion with experimental work on the thermodynamic properties of binary mixtures of condensed gases, it was necessary to know accurately the triple point of argon on the absolute scale. Michels, Wassenaar, Sluyters and De Graaff[1] have recently made a careful determination of this temperature using a platinum resistance thermometer. They suggested that it should be used as a fixed point for thermometer calibrations, and since this proposal has much to recommend it, it is desirable that there should be an independent estimate of the triple point.

Using cylinder gases of the highest purity obtainable, further purified by fractional distillation, we have measured the vapour pressure of oxygen at the triple point of argon, the liquid oxygen being contained in a small bulb surrounded by argon which had just started to melt. The manometer used was that described by Lambert and Phillips[2], and individual measurements of the oxygen vapour pressure at the argon triple point were constant to ± 0·01 mm. The average value was 368·69 int. mm. of mercury with an estimated absolute uncertainty of ± 0·05 mm. Hoge[3] has given values of the vapour pressure of oxygen on a temperature scale based on a helium gas thermometer on which the oxygen boiling point is taken as 90·190° K. (with 0° C. $\equiv$ 273·160° K.). In the range involved, Hoge gives oxygen vapour pressures accurate to 0·1–0·2 mm., corresponding to temperatures accurate to 0·003–0·006°. From his data and the above figure for the oxygen vapour pressure, the triple point of argon is 83·819 ± 0·006° K. This is in good agreement with the value of Michels *et al.* of 83·819 ± 0·001° K.

Aston and Moessen[4] have recently carefully determined the normal oxygen boiling point and obtained a value of 90·154° K., which is 0·036° lower than the figure of the 1948 International Temperature Scale. With their value of the oxygen boiling point, our value for the argon triple point is 83·783 ± 0·006° K.

We have also made repeated measurements of the triple point pressure of argon, obtaining an average value of 516·82 ± 0·04 mm. The figure of 515·7 mm. given by Clark, Din and Robb[5] and used by them to obtain the triple point is undoubtedly too low.

Raman Spectrum of Tetrakistrifluorophosphine-nickel

WE have observed the Raman spectrum of liquid tetrakistrifluorophosphine-nickel, $Ni(PF_3)_4$, prepared as described by Wilkinson[1]. As required for the point group T_d, all the lines of the spectrum are found to be depolarized except three, which are highly polarized ($\rho \sim 0$). This observation provides strong evidence that the arrangement of the four attached phosphorus trifluoride molecules around the nickel atom is regular tetrahedral (cf. nickel tetracarbonyl).

The Raman frequencies of the three polarized lines are 954, 534 and 195 cm.$^{-1}$. They are clearly to be assigned respectively to ν_1 (mainly P–F stretching), ν_2 (mainly symmetrical 'umbrella' PF_3 deformation) and ν_3 (mainly Ni–P stretching). For comparison, the values of ν_1 and ν_2 for the phosphorus trifluoride molecule[2] are respectively 890 and 531 cm.$^{-1}$. Assuming a simple valency force field, the three polarized frequencies of $Ni(PF_3)_4$ may be used for deriving the two bond-stretching force constants $k_{\text{P–F}}$ and $k_{\text{Ni–P}}$ and the deformation force constant k_δ/l^2. The values thus obtained are $k_{\text{P–F}} = 7{\cdot}73$, $k_\delta/l^2 = 0{\cdot}53$ and $k_{\text{Ni–P}} = 2{\cdot}71$ (all in units of 10^5 dynes per cm.). The first two may be compared with the corresponding values for the phosphorus trifluoride molecule, $k_{\text{P–F}} = 5{\cdot}38$ and $k_\delta/l^2 = 1{\cdot}15$, as calculated from ν_1 and ν_2 assuming simple valency forces. The force constant of stretching of the bond between the central nickel atom and each of the attached phosphorus atoms is of particular interest. The corresponding value of $k_{\text{Ni-C}}$ for nickel tetracarbonyl, likewise calculated[3] on the basis of a simple valency force field, is 2·52. Both $k_{\text{Ni-P}}$ and $k_{\text{Ni-C}}$ are in the range normally expected for single bonds, and are thus remarkably low in view of the other evidence which has led to the conclusion[1,4] that nickel–ligand bonds of this kind have appreciable double-bond character.

Retinal Type of Photovoltaic Cell

IT is known that the retina of the animal is a photovoltaic mosaic composed of countless minute individual light receptors. The gradual development of multiple electrode photovoltaic cells may perhaps lead to an actual working model of the retina.

Previously constructed multiple-electrode photovoltaic cells have the seat of their photopotential within each single electrode unit. A typical example of a wet multiple photovoltaic cell is the telephotographic system of Ruben[1], which utilizes the copper/cuprous oxide barrier-layer in each individual receptor unit. Photoemissive mosaic cells such as the television iconoscope, etc., obviously do not approach the retina in principle.

The cell described here is unlike previous multiple-electrode wet photovoltaic cells in that the individual electrodes are completely inert; the seat of the photopotential is apparently in the space charge formed in the volume around the point electrode during irradiation[2]. Certain organic structures when irradiated in solution produce photopotentials with respect to the unirradiated solution, a development from the Becquerel effect. The point electrode here is a potential probe.

The construction of the multiple cell, together with the irradiation box, is shown in Fig. 1. The cell can have as many points as desired on any shape of surface, and only one common dark electrode is required. In Fig. 1, nine point electrodes are shown mounted in a piece of cylindrical 'Bakelite' coil form which is cemented to a glass slide. The bottom electrode is made the common dark electrode. Platinum wire 0·02 in. in diameter is used for all the electrodes. The exposed platinum wire ends inside the compartment are about 0·05 in. long and can be assumed to be points. The cell is cemented together with an epoxy adhesive. A small strip of black electrical or masking tape hides the bottom point from light. The cell is filled with about 0·25 c.c. of a 1 per cent solution of benzoin in 95 per cent ethyl alcohol as one of a series of photoactive solutions[3]. A photopotential as high as 0·15 V. may be generated by each irradiated point with this solution; but in general, sensitivity of the point electrode to the space charge surrounding it during irradiation is more important than the magnitude of photopotential if an analogy to the retina is to be drawn. The wave-length response of the cell is dependent on the photo-active solute used.

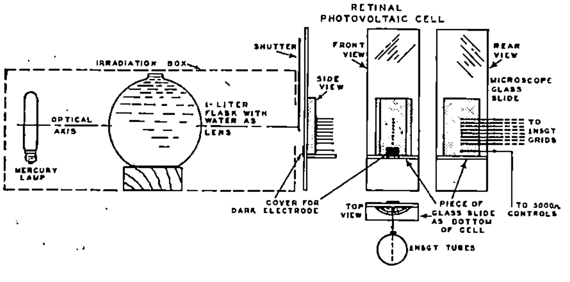

Fig. 1. Retinal photovoltaic cell and irradiation box

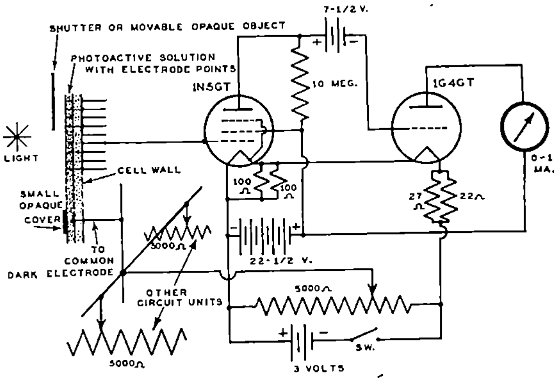

Fig. 2. Amplifier 'brain' unit attached to one electrode point

The cell obviously requires an auxiliary apparatus to indicate that the cell is actually seeing light and a moving object. Fig. 2 shows a simple battery-operated electronic amplifier actually used for each irradiated electrode point. Each milliammeter indicates what its respective point is seeing—light or darkness.

The analogy between the rods and cones of the retina and the point electrodes of this photovoltaic cell, the roles of visual purple and the photo-active solution, and the requirement of a common dark electrode or 'ground' are accented with discretion.

Contrast in the Electron Microscope Image

THE detail seen in a highly magnified electron micrograph is to-day limited more by a lack of contrast in the image than by any lack of resolution in the microscope, which is now usually capable of resolving objects at least as small as 15 A., that is, only a few atoms in diameter. Contrast may be increased either by metal-shadowing the surface of the specimen or by treatment with various reagents. By analogy with the use of stains in light microscopy this latter technique has come to be known as 'electron staining' (perhaps this is an unfortunate, if convenient, term since the analogy is not very close). However, it is still not quite clear what physical property makes a substance likely to be useful for increasing contrast. Published statements say variously that high density, high atomic number, high atomic weight or the presence of atoms of a metal are required. Even the extreme claim that all substances are almost equally efficient in increasing electron density has been argued.

It is unfortunate that exact measurements of contrast in the electron image are not easy to make, and subjective judgments are unreliable except in the rare cases of obviously intense staining. A simple theoretical approach to the problem of contrast has recently been made by Zeitler and Bahr[1], and since this is in reasonable agreement with the few satisfactory measurements that have so far been published[2,3] it seems worth deducing from their formulæ the conditions for a just appreciable increase in contrast in the image of any part of a specimen. If the part considered covers an area S cm.^{2} at right angles to the beam, then we may deduce that a distinct increase in contrast requires the addition of N atoms of atomic number Z uniformly over or through the object where $NZ^{4/3}/S = 5 \cdot 5 \times 10^{17}$ when the microscope works with a high-tension voltage of 60 kV. ($4 \cdot 7 \times 10^{17}$ for 50 kV.; $8 \cdot 25 \times 10^{17}$ for 100 kV.). A reasonably contrasting photographic recording of the image and a small objective aperture have been assumed. This simple formula allows one to predict the effect of adding various amounts of different substances to the specimen and also, in a measure, to reconcile some of the conflicting views on the requirements for contrast.

There are three useful bases on which to compare contrast, and it is important to distinguish which is relevant in any particular case.

(1) Contrast compared on the basis of equal thickness. This is particularly relevant when selecting a material for shadowing the specimen where an adequate increase in contrast with the minimum thickness of deposit is required. If d cm. is the thickness of the thinnest film of material that gives increased contrast, ρ gm.cm.$^{-3}$ the density of the film, A its atomic weight and L Avogadro's number ($6 \cdot 02 \times 10^{23}$), then $NZ^{4/3}/S = \rho d L Z^{4/3}/A = 5 \cdot 5 \times 10^{17}$, that is, $d = 0 \cdot 915 \times 10^{-6} (A/Z^{4/3})(1/\rho)$. Now $A/Z^{4/3}$ is nearly unity for all elements (it varies from 0·57 for uranium to 1·6 for lithium), so that, judged on the basis of equal thickness, the maximum contrast is given by the material with the greatest density. In the particular case of platinum ($A/Z^{4/3} = 0 \cdot 59$, $\rho = 21 \cdot 5$), $d = 2 \cdot 5$ A., which agrees well with practice, where an estimated 5 A. is found to be a suitable thickness for the film of metal-shadowing. This calculation also shows that a useful histochemical technique for the electron microscope might be that of forming small deposits of some dense substance specifically in the tissue; indeed, the few successful techniques so far have been mostly of this type[4,5].

(2) Contrast compared on the basis of equal weight. If an object d cm. thick of density ρ gm.cm.$^{-3}$ can bind p per cent by weight of an added substance, then a detectable increase of contrast requires p to have a value of not less than that given by $(p/100) \rho d L Z^{4/3}/A = 5 \cdot 5 \times 10^{17}$, that is (taking $Z^{4/3}/A$ and the density of the specimen as unity), $p = 9 \times 10^{-5}/d$.

We thus obtain the unexpected result that for a specimen of given thickness the percentage uptake of stain required for contrast is almost independent of the nature of the stain used. For an object about $0 \cdot 5 \mu$ thick (say, a bacterium) a 2 per cent uptake of any stain should increase contrast, and it might be worth trying the usual light microscope stains on such objects viewed with the electron microscope. On the other hand, for a thin section (200 A.) 45 per cent of stain is required. A similar calculation has led Ornstein[6] to claim that, since osmium is only taken up to the extent of about 10 per cent, osmium staining of thin sections must be a fiction. As shown later this conclusion may not be altogether justified, and it certainly conflicts with a deep-set belief of many electron microscopists.

(3) Contrast compared on the basis of equal numbers of molecules. If the object to be stained is d cm. thick and can bind n molecules of stain per cm.^{3}, then for increased contrast $nd(\Sigma Z^{4/3}) = 5 \cdot 5 \times 10^{17}$ where $(\Sigma Z^{4/3})$ is obtained by adding up the values of $Z^{4/3}$ for each atom in the molecule of stain. It is on this basis that different stains would normally be compared. If, as may often be the case, the molecules of stain are bound to the surface of membranes and not uniformly distributed throughout the tissue as has been assumed above, then if n molecules are bound per cm.^{2} of membrane surface, the normal to which makes an angle θ with the beam at any point, contrast results when $n(\Sigma Z^{4/3}) \sec \theta = 5 \cdot 5 \times 10^{17}$. If the tissue is fixed with osmium tetroxide and this is bound on the membranes as the lower oxide $OsO_2(\Sigma Z^{4/3} = 353)$, then when $\theta = 89°$ (that is, in a section where part of a membrane runs almost at right angles to the surface) $n = 2 \cdot 5 \times 10^{13}$ cm.$^{-2}$, or one atom of osmium bound per 400 A.^{2} of the membrane surface will increase its contrast. This is a very plausible figure, so that both in theory and in practice osmium staining of the surface of membranes may well be a fact.

Sintering of Tin Powder

MOST powdered metals will sinter together appreciably when heated to a temperature which, in the absence of extraneous factors, is about three-quarters of their absolute melting point; metals of low melting point tend to be exceptions, however, to this generalization in that they can be heated nearly to their melting point before sintering takes place. There is no evidence, in fact, that tin has ever been observed to sinter[1]. Tin powder is usually made by the atomization of the molten metal and particles of the powder become coated with a film of stannic oxide; this oxide cannot be reduced below the melting point of tin by any atmosphere normally used in sintering. It has already been found[2] that sintering previously pressed powder leads to no further densification of the compact and confers no beneficial properties on it. The inability of tin to undergo sintering has been generally assumed, but never shown, to be due to the presence of unreduced oxide films.

It was decided to test this assumption by attempting to sinter loose oxide-free powder. To obtain such powder, massive white tin was transformed to the grey allotrope at −40° C. in an evacuated and 'gettered' glass tube. Considerable volume changes occur during transformation, and the grey tin formed as a more or less granular powder. This loose powder was re-transformed to white tin at room temperature and shaken to one end of the tube. It was then heated at 220° C., for 48 hr.

The powder had formed a coherent, but friable, mass, which was removed from the tube in one piece. Specimens from this were prepared for micro-examination, which showed much evidence of growth across particle boundaries, indicating that sintering had taken place. It is, of course, to be expected that sintering would take place much more rapidly and completely if the powder were first compacted, but it may be concluded that, in the absence of oxide films, tin powder will sinter when heated.

Thermoelectric Properties of Bismuth Telluride and its Alloys

Previous publications from this Laboratory have described the progress made with bismuth telluride in connexion with thermoelectric refrigeration or generation. With a thermo-junction between *p*-type bismuth telluride and bismuth the maximum temperature difference obtained[1] was 26° C., and between *p*- and *n*-type bismuth telluride[2] 40° C. This corresponded with a figure of merit $\eta\sqrt{\sigma/K}$ of 0·0335 degree$^{-1/2}$. Here η is the thermoelectric power, σ the electrical conductivity, and K the thermal conductivity.

In our work on this compound in 1956 we were able to make *p*- and *n*-type bismuth telluride with greater uniformity and to realize more exactly the optimum thermoelectric power, which is near 200 μV./deg. C. The outcome of this was a maximum temperature difference of 65 deg. C. at a mean temperature of 17° C. The physical properties of the material are consistent with those reported by me at the Garmisch conference in September 1956[3], except that Hall electron mobilities as high as 300 cm.^{2} volt^{-1} sec.$^{-1}$ have been obtained in more recent material.

A temperature difference of 65 deg. C. has been quoted recently by Shilliday[4], of the Battelle Laboratories. In Russian work, Sinani and Gordyakova[5] have quoted a figure of merit of 0·049 for one component of a junction. This was *n*-type, and consisted of an alloy of 80 per cent bismuth telluride and 20 per cent bismuth selenide. The highest temperature difference quoted in Russian work[6] appears to be 70 deg. C., indicating that their *p*-type material is inferior to the *n*-type quoted, since if both components of a junction have a figure of merit of 0·049, the maximum temperature difference is larger than 70 deg. C., as indicated later.

It is to be expected, as discussed by Joffe[7], that in alloys the thermal conductivity will be less than that of either single component, because the substituted atom causes phonon scattering. In favourable circumstances this can be achieved without appreciably increasing the electron scattering. In accordance with this, we have recently studied alloys of bismuth telluride – bismuth selenide, bismuth telluride – antimony telluride, bismuth telluride – bismuth sulphide and also alloys of bismuth telluride – antimony telluride containing either selenium or sulphur. With some compositions both *p*- and *n*-type material with the optimum thermoelectric power has not yet been obtained, and in fact this is the case with alloys giving the lowest thermal conductivity. Taking the most favourable *n*- and *p*-type alloys so far prepared, we have been able to obtain a mean figure of merit of 0·049 for the junction, corresponding with a maximum temperature difference of 80 deg. C. for a mean temperature of 17° C. This results primarily from the fact that substitution of antimony for bismuth lowers the lattice component of the thermal conductivity, K_0, from 0·0157 for bismuth telluride to a minimum of 0·010 ohm. cm.$^{-1}$ deg. C.$^{-1}$ at about 50 atomic per cent of antimony, while the electron mobility is not reduced. Substitution of sulphur or selenium for tellurium in any $(Sb–Bi)_2–Te_3$ alloy causes a further small reduction in K_0, but the amount which can usefully be substituted is restricted because of electron scattering.

Our work on the optical properties[8] indicates that on substituting selenium for tellurium in bismuth telluride, there is a change in band structure near the composition Bi_2Te_2Se, which may be associated with the decrease in mobility on adding selenium because of an increase in inter-valley scattering. We have not so far been able to obtain infra-red transmission through $(Bi–Sb)_2–Te_3$.

I would like to acknowledge the collaboration of several scientists working as a team on this subject. A. R. Sheard is responsible for preparing the material, H. J. Goldsmid for studying thermal conductivity and thermoelectric power, J. R. Drabble for investigating the galvanomagnetic effects, and I. G. Austin for examining the optical properties. P. A. Walker and B. Yates are extending the measurements down to liquid-helium temperatures. In addition to the papers referred to above, some of the more recent work has been published[9], and other papers are in preparation[10].

Mechano-Chemical Anodic Dissolution

Hoar and Hines[1–5] have studied the transgranular stress-corrosion cracking of 18–8 type stainless steels in aerated aqueous magnesium chloride solution (42 wt.-per cent of magnesium chloride) at temperatures of 120–154° C., using thin wires directly stressed in tension. They found rates of crack propagation in the range 0·5–2 mm./hr., similar to those found in other work using much thicker material, and several orders of magnitude smaller than the rate of cracking in mechanical brittle fracture. They suggested that a crack is propagated by the selective anodic dissolution of the highly stressed metal forming its advancing edge, the unstressed sides of the crack remaining relatively unattacked.

By measurements of the electrode potential of cracking wires, and of potential and current density on unstressed wires polarized cathodically with impressed e.m.f., they estimated the current flowing from the surface oxide-film cathode into each crack as of the order of 0·5 μamp.; this, together with the anodic current-density at the advancing edge necessary to give the observed rate of crack propagation by metal dissolution to Fe^{II}, Cr^{III} and Ni^{II}, say 0·4–1·6 A./cm.², leads to reasonable values of the width of the advancing edge, some tens or hundreds of angstroms. The potential measurements also showed that the postulated anodic dissolution of stressed metal at high current density must take place, if it in fact occurs, with only a few millivolts polarization of the anode above its zero-current potential of about −0·15 V. (*N*-hydrogen scale). While there are no grounds for supposing that stressed or even strained metal is, *per se*, much more easily dissolved anodically than unstressed metal, it seemed possible that metal in the act of yielding under stress might be so. Measurements of the overall extension of wires during cracking suggested that the actual strain-rate at the advancing edge of each crack may well be of the order of 10–100 per cent/sec., and it was thus of interest to see whether a macroscopic area of 18–8 type stainless steel yielding at a comparable rate could sustain a high anodic current density of the order of 1 amp./cm.², leading to equivalent metal dissolution, at very small polarization.

We have modified the apparatus of Hoar and Hines[1–5] so that in it a wire may be extended very rapidly while it undergoes anodic polarization in a hot aqueous solution. Arrangements for the simultaneous measurement of extension-rate, electrode potential and current are included, and for the rapid flow of the solution past the wire if required.

When an unstressed wire of 18–8 steel (carbon, 0·09; silicon, 1·00; manganese, 0·78: chromium, 17·1; nickel, 9·2; molybdenum, 0·18; copper, 0·2; nitrogen, 0·06; niobium + tantalum, titanium, $<0{\cdot}05$ wt.-per cent) was polarized anodically in stagnant 42 wt.-per cent aqueous magnesium chloride solution at 154° C. so that the current density was 0·5 amp./cm.², the potential was +0·52 V. and the wire dissolved uniformly over its whole surface to Fe^{II}, Cr^{III} and Ni^{II} with about 100 per cent current efficiency. When a similar wire was treated similarly during its extension at 5 per cent/sec., the potential was + 0·35 V. and similar uniform dissolution occurred. The rapid macroscopic dissolution produced, however, considerable concentration polarization caused by the accumulation of dissolved metal ions in the liquid adjacent to the wire. To reduce this, further experiments, in which similar wires were extended at 5 per cent/sec. while dissolving at 0·5 amp./cm.², were made with the solution forced at 50 cm./sec. past the wire (which was held in the axis of a 1-cm.-diam. glass tube): the potential was now − 0·15 V., very close to the zero-current potential of unstressed 18–8 steel anodes and slightly more negative than the potentials observed during stress-corrosion cracking[1–5], the wire again dissolving uniformly.

These experiments demonstrate that 18–8 steels can dissolve anodically at high current density with very small polarization provided that the surface is yielding rapidly in a direction normal to the direction of dissolution. They provide strong confirmation for the hypothesis of Hoar and Hines for the mechanism of crack propagation; as we shall show in a full report of this work elsewhere, concentration polarization at a very small anode at the advancing edge of a yawning crack is likely to be very small. The experiments also provide an example, on the macroscopic scale, of a mechano-chemical effect: an anodic dissolution that is highly stimulated by the mechanically induced movement of the surface metal atoms.

Similar experiments on pure nickel gave no indication of mechanical stimulation of its anodic dissolution in hot aqueous magnesium chloride solution; significantly, nickel does not suffer stress-corrosion cracking under these conditions. Although 18–8 steel and nickel both have face-centred cubic lattices, the number, distribution and mobility of dislocations and other zones of disarray are clearly different in the alloy and in the pure metal, which may well account for the difference in their behaviour when they undergo simultaneous yielding and dissolution.

Electronic Configuration of Cations in some Distorted Spinels

Two apparently different approaches have been used for explaining the distortion to tetragonal symmetry of some spinels. Both, however, rely on the behaviour of cations having 3*d* electrons. Thus in one the origin of distortion is attributed to the ability of these cations (for example, Mn^{3+}) to form the appropriate covalent bonds with the overlapping oxygen orbitals[1–3]. On the other hand, the second approach relates it to the crystal field effects and Jahn–Teller distortions[4] of ligands around such cations[5].

In what follows the observed electronic configuration of cations in a few cases is examined in the light of these schemes. The analysis of the available magnetic data for $Mn^{2+}[Mn^{3+}_2]O^{2-}_4$ and for the γ-oxide $(Mn^{3+}_2O^{2-}_3)$ showed that Mn^{3+} (d^4) ions at octahedral sites in both the substances have four unpaired *d*-electrons. However, the tetrahedrally situated cations, that is Mn^{2+} (d^5) in the former and

Mn^{3+} (d^4) in the latter had only one and two unpaired electrons respectively[2]. This distribution satisfies the requirement of Mn^{3+} ions at octahedral sites which in virtue of one empty d-orbital would take part in dsp^2 square bonds to produce the appropriate distortion of each elementary octahedron ($c/a > 1$). Furthermore, the cations at tetrahedral sites which have two empty d-orbitals would seem to form d^2sp hybrid (irregular tetrahedral) bonds[2]. This is also in accord with the geometrical requirements where in both the substances the MeO_4 tetrahedra are also distorted and can be described as tetragonal sphenoids[6] with $\alpha_1 = \alpha_2 = 102° 30'$ and $\beta = 113° 34'$, the central cation being equidistant from oxygen ions.

The above electronic distribution of $3d$ electrons in the tetrahedrally situated cations, which seems to be in violation of Hund's rule, can also be justified from the point of view of crystal field theory.

According to this approach[5], the $(t_{2g})^3$ (e_g) configuration of octahedrally situated Mn^{3+} (d^4) ions, having degeneracy with respect to e_g orbitals, gives rise to a Jahn–Teller distortion whereby $c/a > 1$. This is in agreement with observation. However, configurations with highest permissible multiplicity for tetrahedral cations are $(e)^2$ $(t_2)^3$ for Mn^{2+} in $Mn^{2+}[Mn_2^{3+}]O_4$ and $(e)^2$ $(t_2)^2$ for Mn^{3+} in γ-$Mn_2^{3+}O_3$. For the former the Jahn–Teller distortion is zero and for the latter $c/a < 1$. In fact, this distortion of tetrahedral groups will oppose that of octahedral groups. This would conflict with the observed situation where in both the substances $c/a = 1{\cdot}16$. A distortion of the tetrahedral group consistent with $c/a > 1$ is expected from a configuration where there is, in these ions, a single electron in the t_2 orbital (in effect T_2 state). Thus the modified configuration for such ions would be $(e)^4$ (t_2) for d^5 and $(e)^3$ (t_2) for d^4. This distribution is in agreement with the total spin values derived from the magnetic data.

Actually, the distortion of MeO_6 octahedra to give $c/a > 1$ and the corresponding distortion of MeO_4 tetrahedra amounts to the production of a strong crystal field which would favour the low spin-states.

It is expected that a molecular orbital approach which takes into account the essential features of the Jahn–Teller effects would lead to a more consistent picture.

I am grateful to Prof. M. H. L. Pryce for discussions.

Murexide Test in Paper Chromatography

MICHEL[1] found that the purines on a moist filter paper, when treated with chlorine gas for 3 min., dried at 80–90° C. and left in an ammonia atmosphere for a few minutes form compounds which are detectable by their fluorescence in ultra-violet light. A true murexide test, with development of a pink coloration, can be carried out without using chlorine directly, by lightly spraying the paper first with a 10 per cent solution of chloramine *T* (B.P.) and then with *N* hydrochloric acid, followed by heating it in a steam-oven (96–98° C.) until there is no smell of chlorine. The dried paper is then passed slowly over the open mouth of a bottle of concentrated ammonia and heated in the steam-oven for 5–10 min., when the purines will show up as pink spots. It is sometimes necessary to repeat the ammonia treatment and subsequent heating to make the spot visible. Morgan[2] used chloramine *T* as an oxidizing agent for detection of caffeine in the conventional way by the murexide test.

This method will detect uric acid, caffeine, theophylline, theobromine and xanthine in approximately microgram quantities of 1·5, 18, 38, 1 and 7 respectively. When viewed in ultra-violet light the spots show violet fluorescence, and the minimum detectable quantities are reduced to approximately one-third of those quoted above.

We wish to thank the Indian Tea Association for permission to publish this communication.

Acidity of Sprays used in detecting Ketohexoses on Paper Chromatograms

SEVERAL spray reagents are available for the specific detection of ketoses and ketose-containing sugars on paper chromatograms. Probably the most widely used are resorcinol and naphthoresorcinol, originally prepared as sprays in 2 *N* hydrochloric acid by Forsyth[1]. Afterwards, Partridge[2] replaced the hydrochloric acid with trichloracetic acid in order to minimize attack on the filter paper. Heyrovsky[3] has recently reported that β-indolyl acetic acid in trichloracetic acid is also a very sensitive ketose-specific reagent. In work in this laboratory on two fructose-containing disaccharides it has been found that all three of the above reagents, when prepared in trichloracetic acid, failed completely to detect these sugars on paper chromatograms. When the trichloracetic acid was replaced with 2 *N* hydrochloric acid strong positive tests were obtained. The results are listed in Table 1.

Disaccharide *A* was obtained from red clover (*Trifolium pratense*) and yielded fructose only on hydrolysis. Disaccharide *B* was isolated from cultures of *Streptococcus bovis*[4] and yielded both glucose and fructose on hydrolysis. Both sugars were somewhat resistant to acid hydrolysis and required 4 hr. at 100° in 1·5 *N* sulphuric acid for complete hydrolysis. The two disaccharides were applied to

Table 1

Reagent	Acid	Disaccharide *A*	Disaccharide *B*
Resorcinol	Trichloracetic	nil	nil
	2 *N* hydrochloric	bright red	bright red
Naphtho-resorcinol	Trichloracetic	nil	nil
	2 *N* hydrochloric	deep red	deep red
β-Indolyl-acetic acid	Trichloracetic	nil	nil
	2 *N* hydrochloric	strong violet	strong violet

papers as spots containing 20–25 μgm. of sugar, and the sprayed papers heated according to the methods employed by Forsyth[1], Partridge[2] and Heyrovsky[3]. No reaction was obtained with the trichloracetic acid reagents even with prolonged heating times. Fructose and sucrose, under these conditions, reacted readily with all three reagents in either acid, while glucose gave no reaction.

All three reagents appear to have been developed with fructose and oligosaccharides containing the easily hydrolysed sucrose linkage (sucrose and raffinose) as reference sugars. From the results just reported it appears that either free ketose only can react with the reagents or else a specific part of the ketose molecule may be involved in the reaction. In this latter case a stable glycosidic linkage involving this specific portion of the ketose molecule would prevent reaction with the reagents. In either case preliminary hydrolysis would be necessary. The results described suggest that trichloracetic acid, under the recommended conditions, is unable to hydrolyse the more stable glycosidic linkages and thus the stronger hydrochloric acid is necessary.

It is evident that in testing an unknown oligosaccharide for ketoses on a paper chromatogram the stronger acid sprays are necessary. A positive reaction with only the stronger acid reagent may be a useful indication of the strength and possible nature of the glycosidic linkage involved.

Quantitative Determination of Hydroxyproline by Paper Chromatography

RECENTLY, we showed that the quantitative analysis of amino-acids using the maximum colour density method could be accomplished with low errors and good reproducibility[1]. As regards the analysis of hydroxyproline, the accuracy can be considerably improved if the colour development is effected using a ninhydrin–isatin–triethylamine reagent[2] rather than isatin[1].

A solution containing 46·8 mgm. of hydroxyproline in 100 ml. of 10 per cent *iso*propanol was assayed by the paper chromatographic procedure[1]. This procedure employs strips of Whatman No. 1 filter paper, 23 cm. × 57 cm., buffered at *p*H 8·4 and a 40-hr. descending development in the solvent system *m*-cresol buffered at *p*H 8·4.

Eighteen quantitative chromatograms were prepared. Following solvent development and drying at 60° C. for 1 hr., nine of the chromatograms were dipped in 0·4 per cent isatin in water-saturated *n*-butanol containing 4 per cent acetic acid (reagent *A*). The blue colour of the hydroxyproline spots was developed by heating the dipped chromatograms for 10 min. at 100° C. and then storing at room temperature for 24 hr. The maximum densities of the spots were read using a 'Densichron' transmission densitometer (Model 3835*B*, W. M. Welch Scientific Co., Chicago), the red built-in filter, and a 3-mm. aperture.

Table 1. ACCURACY AND PRECISION OF PAPER CHROMATOGRAPHIC DETERMINATION OF HYDROXYPROLINE

Chromatogram	Calculated concentration (mgm./100 ml.)	
	Reagent *A*	Reagent *B*
1	44·9	45·9
2	44·0	47·7
3	47·7	44·9
4	44·9	44·9
5	44·0	44·9
6	49·6	48·7
7	43·1	45·9
8	45·9	46·8
9	43·1	47·7
Average	45·2	46·4
Standard deviation*	2·18	1·41
Deviation from theory†	3·4%	0·9%

* Standard deviation $= \sqrt{\dfrac{N\Sigma X^2 - (\Sigma X)^2}{N(N-1)}}$

† Theoretical value = 46·8 mgm./100 ml.

The remaining nine chromatograms were dipped in a reagent composed of 270 mgm. of ninhydrin, 130 mgm. of isatin and 2 ml. of triethylamine made up to 100 ml. with water-saturated *n*-butanol (reagent *B*)[2]. After heating for 15 min. at 60° C., the maximum densities of the red-purple hydroxyproline spots were read using the 'Densichron' transmission densitometer and no filter.

The results of this comparative quantitative study are given in Table 1. In addition to a marked improvement in the accuracy and precision of the analysis, the use of reagent *B* (the new ninhydrin–isatin–triethylamine reagent) offers a number of other distinct advantages: (1) It is specific for hydroxyproline[2]. (2) It is more sensitive than isatin. The concentration of the standard and unknown solutions spotted on the filter paper are one-half the concentration required when using isatin[1]. (3) The maximum densities of the hydroxyproline spots are greater and can be read immediately after colour development, thus eliminating the 24-hr. colour development period necessary when using isatin.

Iron Content of Hæmoglobin in Iron Deficiency

IN iron-deficiency anæmia insufficient iron is available for hæmoglobin synthesis to proceed at a normal rate. Presumably the primary difficulty is in the synthesis of the prosthetic groups of hæmoglobin, hæm. Since the usual methods of estimating hæmoglobin (spectrophotometry, iron analysis, oxygen capacity) depend upon the hæm group, it appeared possible that the decrease in 'hæmoglobin' observed in this deficiency state might be one of hæm rather than hæmoglobin. Thus, unless globin synthesis was restrained by the absence of hæm, globin molecules with less than the normal four hæm groups might be produced. The studies reported here were undertaken to determine whether appreciable quantities of such a hypothetical incomplete pigment were present.

Table 1

Sample	No. of aliquots	Iron content as average per cent of dry weight ± standard error of the mean
Mother liquor from first crystallization of hæmoglobin from normal rats	2	0·312
Mother liquor from first crystallization of hæmoglobin from iron-deficient rats	2	0·298
Purified (twice crystallized) hæmoglobin from normal rats	5	0·3488 ± 0·0027
Purified (twice crystallized) hæmoglobin from iron-deficient rats	5	0·3364 ± 0·0053
Purified (once crystallized) hæmoglobin from normal human	4	0·3260 ± 0·0017
Purified (once crystallized) hæmoglobin from iron-deficient human	4	0·3173 ± 0·0020
Purified (twice crystallized) hæmoglobin	4	0·3328 ± 0·0028
Purified (twice crystallized) hæmoglobin from iron-deficient human	5	0·3496 ± 0·0028

Rat hæmoglobin was isolated from the heparinized blood of animals rendered iron-deficient by feeding them a mild diet supplemented with an iron-free salt and vitamin mixture. Control animals were fed an identical diet to which ferrous sulphate had been added. The hæmoglobin was crystallized by shaking an alkalinized hæmolysate with toluene, centrifuging, filtering and adjusting the *p*H to 6·8. The crystals were redissolved with the aid of dilute ammonia, and recrystallization was achieved by dialysis against large volumes of iron-free water. Prior to drying for analysis, the crystals were dissolved in iron-free water with the aid of dilute ammonia and the resultant hæmoglobin solution was filtered.

Human hæmoglobin was isolated from the blood of a normal young man and from the blood of a woman with long-standing uncomplicated iron-deficiency anæmia. Crystalline human hæmoglobin was prepared according to Drabkin's method[1]. It was washed briefly in 2·8 *M* phosphate buffer at *p*H 6·8 and was then redissolved in iron-free distilled water, filtered, and dialysed against large volumes of iron-free water. An aliquot of the hæmoglobin was recrystallized by further dialysis against 2·8 *M* phosphate buffer, *p*H 6·8, and was washed overnight in the buffer. The crystals were redissolved in 2·0 *M* phosphate buffer *p*H 6·8, filtered, and dialysed against several large volumes of iron-free water.

2–5 aliquots of each hæmoglobin solution were dried to a constant weight at 110° C. and were then wet-ashed with concentrated sulphuric acid and hydrogen peroxide. In the case of human hæmoglobin solutions, residual potassium phosphate represented less than 1 per cent of the dry weight as estimated by phosphorus analysis. A correction for the weight of this salt was made. Iron determinations were carried out colorimetrically with *o*-phenanthrolene, using a modification of the method of Barkan and Walker[2]. The iron content of the hæmoglobin samples is presented in Table 1.

Assuming that the pigment in the destromatized hæmolysate is representative of the pigment inside the intact red cell, the results of these studies demonstrate that most, if not all, of the pigment in iron-deficient red cells has a normal iron content. It is apparent that the nearly identical iron content of the purified hæmoglobin solutions from normal and iron-deficient subjects cannot be due merely to failure of an incomplete hæmoglobin to crystallize, since there was very little difference in the iron content of the mother liquors from the first crystallizations of the rat hæmoglobin. Thus in iron deficiency a defect in the hæm synthesis appears to limit somehow the synthesis of globin.

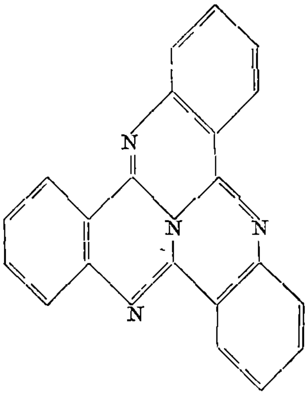
Carcinogenicity of Tricycloquinazoline

Tricycloquinazoline (I) has hitherto been prepared from indazole and copper powder[1,2], from *o*-aminobenzaldehyde and ammonium chloride[3] and from *o*-cyanoanilinium toluene-*p*-sulphonate[2]. We now find that it is readily formed in simple pyrolytic reactions. For example, methyl anthranilate was refluxed into a red-hot tube; a benzene solution of the resulting tar, after removal of its constituent acidic and basic fractions including methyl anthranilate, furnished 0·053 per cent of pure tricycloquinazoline by chromatography on alumina.



(I)

It was also produced, in the yields given, by the action of heat on the following compounds or mixtures: ammonium anthranilate (0·083 per cent), anthranilamide (0·73 per cent), anthraniloylanthranilamide (5 per cent), anthranilamide toluene-*p*-sulphonate (20–25 per cent), methyl anthranilate and ammonium benzenesulphonate (5–16 per cent), ammonium anthranilate and ammonium benzenesulphonate (0·11 per cent), anthranilic acid and ammonium benzenesulphonate (0·086 per cent), anthranilamide and ammonium benzenesulphonate (12 per cent). In each instance the product was authenticated by its melting-point and mixed melting-point, by its characteristic ultra-violet light absorption and by its R_F value.

Tricycloquinazoline can be sublimed unchanged at red heat at atmospheric pressure and is resistant to oxidation. This substance is a representative of a class of polyazapolycyclic hydrocarbons which have not previously been tested for carcinogenic properties, and so the activity has been examined following subcutaneous injection in the rat.

The compound was injected subcutaneously as a suspension in olive oil (10 mgm./ml.) into 30 Wistar

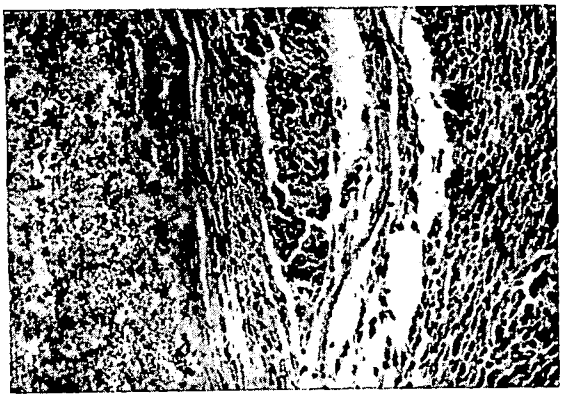


Fig. 1. Photomicrograph showing relation of neoplastic tissue to injected tricycloquinazoline. (× *c.* 90)

rats, 7–11 weeks old and equally divided with respect to sex. Because of the persistence of the material at the site of injection, rats received only four monthly injections, representing a total dosage of 40 mgm., and were then observed for 26 months.

The injected tricycloquinazoline proved to be extremely resistant to metabolism, and subcutaneous cysts containing the compound remained at the site of injection during the whole period of the experiment (22–26 months). In two experiments where attempts were made to recover tricycloquinazoline from injected rats after 22 months, in each case a total of 36 mgm. out of 40 mgm. injected was recovered from the local lesion in an unchanged form.

Tumours were observed in 27 per cent of treated rats during the period of the experiment and the tumour-induction period was relatively high. The first tumour appeared 14 months after the first injection, while the majority of the tumours developed between the sixteenth and twenty-fourth months. All these tumours were undifferentiated spindle-cell sarcomata which had arisen at the site of injection. Tricycloquinazoline causes a low-grade inflammatory reaction in the surrounding connective tissue, with ultimate formation of a cystic space surrounded by fibrous tissue. The inactivity of the compound is indicated by its demonstration by fluorescence microscopy as long as 26 months after injection. Histological studies enabled the close relation of the tumours to be seen (Fig. 1).

The latent period for tumour induction with tricycloquinazoline is considerably greater than that observed with polycyclic hydrocarbons[5]. This may be due to the extreme inertness of the compound, and it is interesting that similar latent periods have been observed for tumour induction by implants of synthetic polymers, which are also chemically unreactive[6].

Although it is not suggested that the carcinogenic activity of these various substances is due to a common mechanism, it would appear that, by virtue of its chemical inertness, the carcinogenic response produced by tricycloquinazoline more closely resembles that caused by plastics[6] and metals[7] and cannot be directly compared with the activity of the more readily metabolizable polycyclic hydrocarbons.

In view of the wide occurrence of methyl anthranilate in plants[4], and the fact that tricycloquinazoline can be readily prepared from it by the action of heat, the products of pyrolysis of plant material are now being examined for the presence of tricycloquinazoline. Further studies are also in progress to determine the carcinogenic activity of the compound administered by several routes in mice and rats.

A Micro-electrophoretic Method

A MICRO-ELECTROPHORETIC technique has been developed which is sensitive, simple and rapid and does not require any elaborate apparatus. Very clear results can be obtained with samples of the order of fractions of a micro-litre with a protein content of 10 μgm. and even less. The technique is a combination of the membrane filter electrophoresis[1] and, in particular, of the small-scale technique[2], with the use of a very sensitive stain—'Nigrosin'[3]. All details of the membrane-filter electrophoresis apply as well to the micro-technique.

A horizontal electrophoretic tank for small-scale membrane-filter electrophoresis, with a bridge gap of 8 cm. is used. The buffer compartments run through the whole length of this tank, convection currents are considerably reduced and more efficient vapour saturation and cooling are provided.

The supporting medium consists of cellulose acetate-membrane filter strips (Oxo, Ltd., 16 Southwark Bridge Road, London) 10–12 cm. × 2·5 cm., with strip-holders lined with filter paper acting as wicks. Longer or wider strips can be used (and may be easier to handle). 120 V. applied for about two hours provides a pattern length of approximately 5–6 cm.

The sample is applied by means of a very fine calibrated capillary, micro-pipette or micro-syringe, about 2 cm. from the cathode end. The position of the sample is important and partly determines the pattern. The size of the sample can vary from 0·0001 ml. to about 0·008 ml. (0·1–8 μl.). Staining is carried out in very dilute 'Nigrosin' solution (0·005 per cent in 2 per cent acetic acid) for about one hour, the time being judged best by experience. The strip is washed in 2 per cent acetic acid, blotted and dried. 'Nigrosin' is more suitable for small samples. For samples containing more than 70 μgm. of protein conventional stains are to be preferred.

Patterns obtained with the method described are shown in Fig. 1. Clear separation patterns were still obtained on serum samples not exceeding 0·0001 ml. containing about 5–10 μgm. of protein. Two pre-albumin fractions could be clearly demonstrated in human serum (Fig. 1*b*). An important feature of this technique is that with small quantities of protein used some minor protein fractions become unmasked.

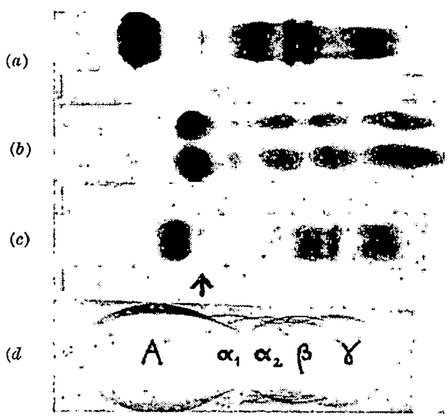

Fig. 1. Human serum, veronal buffer *p*H 8·6, *a*, *b*, *c*, 'Nigrosin' stain, *d*, azocarmin. Contact prints from uncleared strips. (*a*) 0·5 μl. 30 μgm. protein; (*b*) two pre-albumin fractions, 30 and 40 μgm. protein; (*c*) small post-albumin fraction (indicated by arrow) 10 μgm. protein; (*d*) micro-immuno-electrophoresis on 0·0025 ml. serum (180 μgm. protein)

A post-albumin fraction, for example, has been found in most of the human sera investigated (Fig. 1*c*).

The micro-technique described above can also be applied to immuno-electrophoresis (Fig. 1*d*). This is performed in a manner similar to that reported in a previous paper[4], taking into account the smaller size of the strip. The thickness of the agar layer should not exceed 1–2 mm., and the distance between the electrophoretic and antiserum strips is reduced to 3–5 mm., the width of the antiserum strip being about 1 mm.

Formation of Lactulose and Tagatose from Lactose in strongly heated Milk

In recent years it has been shown that reductones, furfurals and other related substances formed in heated milk are sugar fission products[1,2]. The mechanism by which lactose is degraded to these products has interested food chemists, but nothing is known of the transformation of carbohydrates in heated milk, in spite of considerable attention paid to them in normal cow's milk[3-5].

In order to confirm the secondary formation of carbohydrates in heated milk, the browning whey from autoclaved milk (120° C., 10 hr.), from which the curds had been removed, was chromatographed on Tōyō No. 50 filter paper by the ascending technique using the mixture *iso*propanol/pyridine/acetic acid/water (8 : 8 : 1 : 4)[6], and phenol saturated with water as solvent systems. The chromatogram was coloured by spraying with resorcine and aniline hydrogenphthalate reagents. The control sample was prepared from raw milk by a method essentially similar to that described by Sasaki and Taniguchi[5]. In the case of heated milk the chromatograms gave two new spots corresponding to tagatose and lactulose, and the intensity of the galactose spot was greater than that of raw milk. The lactose and glucose spots were less intense than in raw milk. These results are not sufficient to identify the newly formed carbohydrates. However, they indicate clearly that the same carbohydrates are formed secondarily from lactose in milk during heating in the autoclave.

The isolation and identification of these carbohydrates were carried out by Whistler and Durso's[7] and Samuelson and Sjoström's[8] methods. The sample from autoclaved milk (120° C., 8 hr.), desalted by passing it successively through columns of the ion exchange resin 'Amberlite-*IRA* 410' (OH^- form) and 'Amberlite-*IR* 120' (H^+ form), was poured into a column packed with a mixture of equal weights of 'Sagi' activated charcoal and 'Celite No. 535' filter aid. It was then developed with water followed by 5 per cent ethanol. These eluting fractions were passed separately through a column of 'Amberlite-*IRA* 410' (HSO_3^- form) and evaporated under reduced pressure. The crystalline carbohydrates isolated from the resultant syrups by methods given in the literature[9,10] were identified, by the determination of physical constants in conjunction with the results of the formation of characteristic derivatives, as *d*-tagatose and lactulose, from the water and ethanol fractions, respectively. These results are shown in Table 1. Galactose was identified in the water fraction as *p*-tolylhydrazone.

On the basis of these results, it seems reasonable to assume that the successive transformation of lactose to lactulose, galactose and tagatose in heated milk occurs not only in accordance with the Amadori rearrangement (as shown in previous papers[11]) but also *via* the de Bruyn and van Ekenstein reaction in the milk protein–lactose system. These findings are supported by the facts that tagatose was not formed while lactulose and galactose were, from *p*-tolyl–*iso*lactosylamine, the Amadori rearrangement product of *p*-tolyl–lactosylamine[12], under the conditions described above. Tagatose is doubtless the de Bruyn and van Ekenstein reaction product of galactose. Since lactulose has not been hitherto reported as a constituent of any natural product, while naturally occurring tagatose has recently been discovered in the gum

Table 1. Identification Data of Crystalline Ketoses eluted from Carbon Column

Synthesis of Phlorin and other Phenolic Glucosides by Plant Tissues

ALTHOUGH phloroglucinol itself seldom occurs in plants it has been implicated in the biosynthesis of ring *A* of the flavonoid compounds[1,2]. In the course of a study of the metabolism of the glucoside, phloridzin, in *Malus*, leaf disks were fed phloroglucinol together with glucose labelled with carbon-14, and although phloridzin synthesis was unaffected a new compound was detected in chromatograms which has been tentatively identified as phlorin[3], the glucoside of phloroglucinol.

The methods used were as follows: 4 or 5 leaf disks, 1·2 cm. diam., obtained with a Ganong leaf punch, were infiltrated under vacuum with tap water, blotted and placed in 0·6 ml. of a solution of 600 μgm. phloroglucinol and 50 μgm. (1 μc.) labelled glucose contained in a small Petri dish. The dish was covered and placed in the light at room temperature. After 24 hr. the disks were removed, washed thoroughly with water and extracted for ½ hr. with boiling 80 per cent ethanol. The ethanolic extract was reduced in volume by means of an air jet at room temperature and applied, without further purification, to Whatman No. 1 paper for chromatography. The solvents were phenol saturated with water for the first direction and butanol/acetic acid/water (4 : 1 : 5 v/v) for the second.

Phlorin was detected on chromatograms by colour reactions with vanillin in concentrated hydrochloric acid[4], diazotized sulphanilic acid[5] and diazotized *p*-nitroaniline[6]. Radioactive phlorin was eluted from chromatograms with hot ethanol and hydrolysed with either 2 *N* hydrochloric acid or emulsin after removal of the ethanol. Chromatography of the hydrolysis products gave phloroglucinol and labelled glucose. Successful hydrolysis with emulsin showed that the compound was a β-glucoside. When phloroglucinol labelled with carbon-14 and inactive glucose were fed to disks, a radioactive spot, identical with the one obtained from phloroglucinol and labelled glucose, was obtained.

Table 1. DISTRIBUTION OF CARBON-14 IN 80 PER CENT ETHANOL-SOLUBLE FRACTION OF LEAF DISKS OR SEGMENTS FED LABELLED GLUCOSE AND PHLOROGLUCINOL

Leaf disks or segments	Per cent radioactivity of 80 per cent ethanol-soluble fraction				
	Phlorin	Glucose	Fructose	Sucrose	Glucitol
Adiantum macrophyllum	11	<1	<1	82	—
Pinus resinosa	62	1	—	37	—
Briza media	27	1	—	64	—
Pelargonium hortorum	76	3	—	1	—
Kalanchoë punctata	3	46	42	9	—
*Gerbera jamesonii**	82	1	—	5	—
Malus sylvestris	29	1	—	5	64

* When leaf disks of this plant were fed phloroglucinol labelled with carbon-14 and inactive glucose under the same conditions, 90 per cent of the radioactivity of the 80 per cent ethanol-soluble fraction was in phlorin.

That this ability to synthesize phlorin is not peculiar to apple-leaf tissue is shown in Table 1. It was found that phlorin synthesis occurred not only in the margins but also in the central regions of the disks, and, moreover, light was not necessary to effect this synthesis. Except for *Adiantum*, free phloroglucinol was not detected in any of the other plant extracts. When starved leaves, that is, leaves on plants maintained in the dark for 48 hr., of *Pelargonium hortorum* or *Gerbera jamesonii* were used, however, phlorin synthesis was found to decrease, and free phloroglucinol accumulated in the tissues. This occurred even in the presence of exogenous glucose.

Although other sugars such as fructose, galactose, rhamnose, arabinose or xylose were substituted for glucose, no glycoside other than phlorin was detected on chromatograms.

Other phenols, including orcinol, resorcinol, hydroquinone, salicyl alcohol, *p*-hydroxybenzaldehyde and vanillin were similarly fed with labelled glucose to leaf disks of *Malus* and *Gerbera*. Each phenol gave rise to what appeared to be the respective glucoside regardless of whether it occurred naturally in the plant, and appeared as a distinct, intensely radioactive spot on the chromatogram.

So far as we know, this ready synthesis of phenolic glucosides by plant tissues has not been described, although Dr. A. E. Schwarting of the University of Connecticut (private communication) has found that salicyl alcohol, when fed to twigs of *Salix nigra*, gives increased amounts of salicin in the bark.

Phenols have been prominent in theories of disease resistance in plants[7–13]. Disease resistance has been attributed to either an increased production of phenols in healthy tissue adjacent to regions invaded by the parasite or to a naturally high phenol content of the host. The increase in free phenols often observed in healthy tissue of parasitized plants may be due to an inability to 'detoxify' phenols liberated by enzymic hydrolysis of the natural glycosides of the plant. The inability to 'detoxify' phenols may be caused by glucose depletion as a result of metabolic activity of the pathogen. These phenols permeate both host and parasite tissues. The extent to which pathogenic bacteria and fungi either metabolize or 'detoxify' phenols is not clear. Recently, certain phenolic acids, hitherto considered to be characteristic of higher plants, have been detected in a bound form (possibly as glycosides) in uredospores of wheat stem rust[14]. It is possible that these compounds are formed in the fungus through glycosidation subsequent to the absorption of phenolic acids. If phenols are to be implicated in theories of disease resistance it would appear that studies of the metabolism of these compounds in both host and parasite may be of the greatest importance.

We thank the National Research Council of Canada for financial support of this work and for a bursary to one of us (C. R.). We are also pleased to acknowledge, with thanks, financial support from the Department of Agriculture, Canada. We are grateful to Dr. A. C. Neish, National Research Council of Canada, for a generous gift of labelled phloroglucinol.

Effects of Clipping and Spraying on Various Homœothermic Responses of Rabbits at an Elevated Environmental Temperature

The relative effects of clipping and spraying on evaporative and non-evaporative cooling have been measured on rabbits at an elevated air- and body-temperature. Under such conditions most of the heat loss is by evaporative cooling.

Rabbits were maintained in individual cages in the alley of the University of Missouri Climatic Laboratory at 103° F. and 15 per cent relative humidity, in an air velocity of 50 ft./min. Drinking water and rabbit feed (pellets) were available *ad libitum* from hopper-type feeders and waterers. However, at 103° F. air-temperature the rabbits consumed no food, except occasionally after spraying.

Before exposure to an air-temperature of 103° F., four of the eight experimental rabbits were sheared as closely as possible with small animal clippers. After being at 103° F. for 4–5 hr., the animals were sprayed manually with an atomizer (15 lb./in.^{2} air pressure), using water at room-temperature (103° F.). Each rabbit was sprayed for 5 min. using only enough water to produce a fine mist. Conduction between the skin and (spray) water was thus not likely to be an appreciable factor in loss of heat.

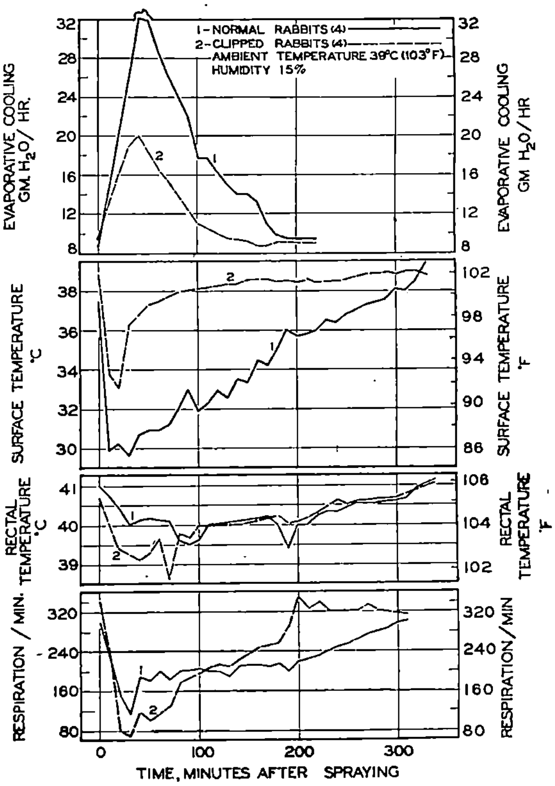

Fig. 1. Influence of spraying on various reactions of normal and clipped rabbits

Respiration-rates were measured by counting the flank movements of the animals in the cages. Each point in Fig. 1 represents an average of three determinations. Surface temperatures were taken by the Hardy dermal radiometer. Evaporative cooling (insensible weight-loss) was measured by weighing the animals on a large, sensitive, 'chainomatic' scale placed in the Climatic Laboratory. Rectal temperatures were taken by clinical thermometer.

Merely clipping the rabbits at 103° F. showed no striking effect on the homœothermic responses of the animals, although it was beneficial. Average values for the clipped rabbits at that temperature were: respiration-rate, 335 per min.; surface temperature, 38·8° C.; rectal temperature, 40·68° C.; and evaporative cooling, 9·26 gm. water/hr.; corresponding values for the normal rabbits were: respiration-rate, 290 per min.; surface temperature, 37·5° C.; rectal temperature, 41·1° C.; and evaporative cooling, 8·66 gm. water/hr. Clipping exposed the warm skin directly to the ambient air, resulting in a slightly greater rate of evaporation, a greater rate of non-evaporative cooling, and a lower rectal temperature. Respiration-rates were higher in the clipped rabbits. All these measurements indicate some benefit from clipping at high temperature.

However, there were striking differences in the responses of clipped and normal rabbits to spraying. Fig. 1 (top) shows the evaporative cooling of New Zealand white clipped and unclipped rabbits after spraying. Rabbits with normal coats showed a great increase in evaporative cooling in contrast to the clipped animals (cf. curves 1 and 2 in Fig. 1), amounting to approximately fourfold 50 min. after spraying for the normal rabbits, and only twofold for the clipped animals. These increased rates of evaporative cooling after spraying persisted for about 125 min. for clipped rabbits and 175 min. for normal rabbits. Thereafter both curves return to their initial level for the environmental temperature of 103° F.

The surface temperature (Fig. 1, second section) was lower for the normal-coated rabbits, for about 275 min. after spraying, due to the greater surface evaporative moisture. There was, presumably, less loss from non-evaporative cooling.

The lower rectal temperature of the clipped rabbits reflects a greater immediate physiological response to spraying than in normal rabbits (Fig. 1, third section) for the first 75 min. after spraying. Thereafter less difference between the rectal temperature of clipped and normal rabbits was noted. A greater immediate benefit of the clipped rabbits to spraying is also shown in the respiration-rate (Fig. 1, bottom section), which, however, increases considerably after about 100 min.

Thus the physiological and physical responses of the clipped and normal rabbits to spraying are quite different. The more sensitive respiration-rate of the normal rabbits 145–300 min. after spraying demonstrates the value of wet fur, the action of which may be compared to that of a moist sponge-rubber blanket[1]. Following spraying, the rectal temperature and respiration-rate declined rapidly, though only temporarily (Fig. 1), particularly in clipped rabbits. The major cooling factor responsible for the decline in this case was undoubtedly the increase in evaporation, since in both clipped and normal rabbits their surface temperatures (radiometer reading) were below that of the environment.

Validity of Motokawa's Technique for investigating Retinal Function

IN the past decade, Motokawa and co-workers have published in about sixty papers the results of a new technique for investigating retinal function. Gebhard[1] has published a review of this subject. Michaels[2] claims to have confirmed Motokawa's observations. Recently, Riggs *et al.*[3], and ourselves[4], working independently, have failed to confirm the most important of Motokawa's results. We believe that there are serious flaws in Motokawa's and Michaels' technique and that their experimental results may be artefactual.

Motokawa's technique is based on the curve of the change of threshold for electrical stimulation of the human eye after various types of light stimulation. The threshold is said to be minimal 1 sec. after red light, 2 sec. after white and green and 3 sec. after blue.

Both Motokawa and Michaels use very highly trained subjects and rather unusual psychophysical methods. Motokawa starts with a stimulus well above threshold and reduces the intensity in fairly large (10 per cent) steps until the suspected threshold is approached; the step size is then reduced (to about 1 per cent) and, when requested by the subject, a zero stimulus may be given for comparison. Michaels gives stimuli which are alternately above and below the threshold and approaches the threshold by a method of "successive approximations". Motokawa's method will certainly contain a source of error due to the greatly increased probability of finding a threshold when the large steps are changed to small ones. Michaels' results would be affected by the range of high and low intensities selected by the experimenter and by any sequential response habits, such as alternation, of the subject. The use of very highly trained subjects could set up unconscious subject-experimenter interaction, since the long training period seems to continue until the subjects give the 'correct' results. The consistency of threshold determinations by Motokawa's subjects is much better than that found for any other visual threshold. This in itself induces a feeling of uneasiness about the methods used.

Riggs *et al.* used a few trained subjects and attempted to reproduce Motokawa's technique as closely as possible. However, they had a rigidly defined threshold criterion, and they always reduced the intensity of the stimulus by a constant fraction. This meant that they gave, in a single run, rather more stimuli well above threshold than did Motokawa. Kohata *et al.*[5] have now claimed that the relatively intense stimuli used at the beginning of the run produce an after-effect which obscures the fall in the phosphene threshold and increases the variability of the measurement.

In our own experiments, we reduced the intensity of the stimulus by equal steps on a linear scale, and each intensity was presented only once. The sequence was stopped after the subject had failed to see three consecutive stimuli. A variety of threshold criteria was applied to our data (including taking the lowest positive response), but all gave essentially the same result. We used both naïve and experienced subjects and intervals between the light flash and the electrical stimulus of 1, 2, 3, 4 and 9 sec. In almost all our subjects the threshold was lowest in the 1-sec. condition and rose in an approximately exponential manner for the longer intervals no matter what the colour of the light flash, and even if the light were replaced by a bell. A very similar result was obtained also for an auditory difference threshold following a brief flash of light. We interpreted this effect as being due to the initial light or bell acting as a warning to the subject when to expect the stimulus. Following this interpretation we found that the phosphene threshold was completely unaffected by a preceding flash of light, provided a bell rang at a constant interval (1 sec.) before the electrical stimulus. This condition provided our most stringent test of Motokawa's basic observation, since it excluded the warning effect.

We have met the objection of Kohata *et al.* by repeating this experiment, but approaching the threshold from below, to exclude the possible after-effects of strong stimuli[4]. We did not find in either case any effect of the light on the electrical threshold, nor was there any marked change in the variability of the threshold measurements. The results of these experiments are shown in Table 1. It may be that only the lowest of the multiple thresholds which Motokawa claims to have observed will give the Motokawa phenomenon, and that Riggs *et al.* and ourselves may have observed higher and inappropriate thresholds. However, neither we nor Riggs *et al.* have been able to record multiple thresholds even in highly trained subjects.

Table 1

Interval between light and electrical stimulus (sec.)	1	2	3	4	9
Mean threshold when approached from above (log μamp.)	2·0535	2·0425	2·0629	2·0633	2·0728
Mean standard deviation	0·0628	0·0688	0·0641	0·0547	0·0737
Mean threshold when approached from below	2·1223	2·1422	2·1111	2·1255	2·1564
Mean standard deviation	0·0488	0·0299	0·0473	0·0682	0·0407

The number of subjects in the two conditions were 10 and 6 respectively. Each subject gave four estimates of each threshold. Unfortunately they were largely different subjects so that inter-subject variability cannot be ruled out in comparing the two sets of figures.

The most stringent test of the multiple threshold hypothesis is obviously to present a range of intensities near the threshold in random order (method of constant stimuli) and to see if the probability of seeing changes monotonically with the intensity or in a series of steps. Riggs *et al.*[3] and Howarth[6] have done this each using just one experienced subject and find that the probability of seeing changes in a 'normal' manner is 25–75 per cent between intensities of 110–145 μamp. There is no evidence of discontinuities in these curves.

Passage of Phosphate through the Human Tooth

The first experiments using isotopes on teeth appear to be those of Hevesy *et al.*[1]. They administered phosphorus-32 to two human subjects, and to cats and rats, then found it in both dentine and enamel, attributing this finding to ion exchange. Later work with other isotopes (those of hydrogen, iodine, sodium, calcium, sulphur, carbon and potassium) showed that labelled ions may pass into tooth structure, more readily into dentine than into enamel. However, apart from Hevesy *et al.*, such work seems to have been restricted to animals (see ref. 2 for summary).

The present investigation describes work on the movement of phosphate through human teeth. The teeth have been tested as quickly as possible after removal from the mouth. The pulps of such teeth are known to respire[3]: $Q_{O_2} = 0 \cdot 31$, $RQ = 0 \cdot 93$.

Sound bicuspid teeth from subjects aged between 9 and 12 years were used, and, within 10–15 min. of removal, preparation of the teeth was completed. Crowns and roots were separated at the gum-line, cutting across the central root-canal; crowns were used. The bulk of the pulp was then removed from the pulp chamber leaving it lined by odontoblasts. Four methods of examination (the first three microscopical) were used for confirming the presence of odontoblasts *in situ* in such preparations: (1) de-pulped teeth were examined after staining with methylene blue, when odontoblasts have been seen *in situ*; (2) scrapings from pulp-chamber walls, spread on glass slides and stained with methylene blue, show odontoblasts; (3) de-pulped teeth were sectioned by microtome (after decalcification); examination of stained sections shows a ring of odontoblasts *in situ* lining the pulp-chamber; (4) de-pulped teeth were decalcified and examined by electron micrograph, when odontoblasts are seen *in situ*[4].

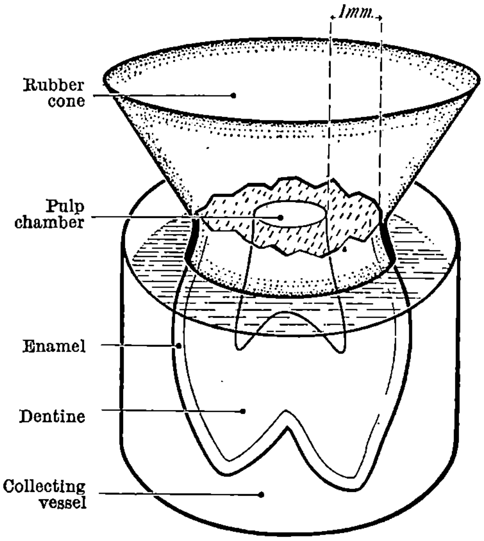

Fig. 1. Test of passage of phosphorus-32 through tooth. The labelled phosphate is added to the pulp chamber by a fine pipette. Later the tooth-crown is removed when the collected fluid is examined for radioactivity

On being de-pulped, a tooth crown intended for test was at once filled with Krebs–Ringer solution saturated with 95 per cent oxygen/5 per cent carbon dioxide at 37°. The tooth crown was then clamped in a rack, and by means of a pinion lowered into a small vessel of 1·6 ml. Krebs–Ringer at 37° so that the crown is submerged to the cut and exposed dentinal aspect, while this remains above the fluid level (Fig. 1). Splash is avoided by fitting a thin rubber cone with a 1-mm. hole in the apex,

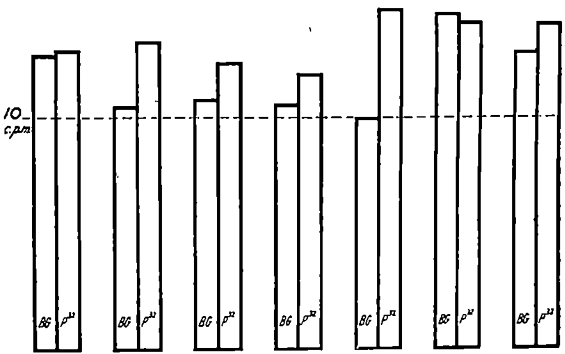

Fig. 2. Collected labelled phosphate and background compared on passage of labelled phosphate through each of seven teeth

Table 1. Results of Seven Tests

Experiment No.	$\overline{X}$ c.p.m. of collected phosphate	Background (c.p.m.)
1	12·9	12·7
2	13·3	10·5
3	12·4	10·8
4	11·9	10·6
5	14·7	10·0
6	14·1	14·5
7	14·2	12·9

around the tooth ; the cone extends about 1·5 cm. upwards. Creep is avoided by tying a thin, strong cotton thread tightly around and close to the base of the rubber cone.

Inorganic phosphate labelled with phosphorus-32 was now added to the Krebs–Ringer in the pulp-chamber. Every 5 min. the tooth-crown was racked up and a fresh vessel of Krebs–Ringer brought underneath, when the tooth-crown was lowered into it. The contents of the pulp-chamber were changed for fresh Krebs–Ringer about every 15 min. A test series usually comprises 20–24 such vessels, each of 1·6 ml. Krebs–Ringer, which collect any labelled phosphate that passes through the tooth. A test takes in all about 2 hr. The collections of fluid were dried and their radioactivity determined. Background counts were made before, during and after tests ; all counting periods were of 5 min. duration.

Passage of phosphorus-32 is seen to occur through human teeth when introduced in inorganic form, and results are shown in Table 1 and Fig. 2. In each case the c.p.m. shown is the mean of all the counts made on the one tooth collection. Actual counts of phosphorus-32 range from 9·4 to 62·6 c.p.m., while backgrounds ranged from 8·8 to 17·2 c.p.m. Combining the tests[5] gave a χ^2 of 51·7 on 14 d.f., which is highly significant, $P < 0{\cdot}001$.

In one test, phosphorus-32 was collected for the usual 5-min. period, c.p.m. being 14·2 ; a 30-min. collection was then made, which gave a mean of 15·4 c.p.m., reasonably close to the mean, and which may indicate a steady rate of passage. In each experiment, activity was determined of each of the vessels (about twenty) containing phosphorus-32 which had passed through the tooth ; the mean of each of these series is shown in Table 1 and Fig. 2.

Thus passage of phosphorus-32 through odontoblasts, dentine and enamel occurred in these tests on human teeth which are believed to be alive. However, such passage is limited in extent, any part played by the odontoblasts being unknown, though the use of suitable fluid media is aimed at keeping the cells viable. There are here two supporting observations to be kept in mind : (1) under suitable conditions tooth-pulp respires for some hours after removal of the tooth from the body ; (2) de-pulping of a tooth leaves odontoblasts *in situ*, each cell held in place by the long cell-process extending through the dentine as far as the enamel.

From the present work, enamel appears more permeable than has hitherto been supposed, though little comparable work has been found in the literature. This permeability may well be related to the inhomogeneity of enamel. Saunders *et al.*[6], and Symons describe two kinds of ameloblasts in developing enamel. During development, one kind of cell (a minority) shows special staining reactions and also a higher ribonuclease activity[7]. While completed enamel is devoid of cells, residual pathways of enzymic activity greater than the bulk of enamel could facilitate passage. Histochemical examination of enamel may yet provide evidence here. Autoradiography of human teeth through which phosphorus-32 has passed presents difficulties not completely overcome so far.

My thanks are due to Prof. R. Douglas Wright, Sir Arthur Amies and the University of Melbourne Research Fund.

Blocking Effect of Morphine on the Secretion of Thyroid-stimulating Hormone in Rats

The ability of morphine to inhibit certain pituitary functions has been established. The administration of morphine on the day of pro-œstrus resulted in the suppression of ovulation[1]. It is also possible by pre-treatment with morphine to prevent the secretion of adrenocorticotrophic hormone which follows an injection of adrenaline or other stress[2]. Sawyer *et al.*[3] have observed that morphine in doses sufficient to block the activation of the pituitary depressed the electrical activity of the central nervous system and also of the hypothalamic centres. The present experiment was designed to ascertain whether morphine is capable of blocking the secretion of the thyroid-stimulating hormone of the pituitary also.

Male rats of the Wistar strain, weight 140 gm., were used in this investigation. The right lobe of the thyroid and half the isthmus were removed under ether narcosis and the animals were divided into two groups. The control group received a daily dose of 0·1 ml. saline solution subcutaneously, while the other group received morphine in a daily dose of 2 mgm. per rat. After 14 days the rats were injected intraperitoneally with 25 μc. of iodine-131 and 24 hr. later were exsanguinated from the abdominal aorta. The following parameters were evaluated for the remainder of the thyroid : weight of the thyroid lobe, epithelial cell height, uptake of iodine-131 in the thyroid and percentage of iodine-131 which

Table 1

Group	Control (8 rats)		Treated (17 rats)	
Partial thyroidectomy	Before	After	Before	After
Weight of one lobe of thyroid (mgm./100 gm.)	4·05* ± 0·25	4·76 ± 0·40	4·32 ± 0·17	4·46 ± 0·16
Epithelial cell height (μ)	9·74 ± 0·32	11·27† ± 0·46	9·63 ± 0·26	9·27 ± 0·64
Thyroidal uptake of iodine-131 (per cent/100 mgm.)		61·24 ± 8·04		33·02‡ ± 5·53
Protein bound iodine-131 (per cent)		0·1313 ± 0·0114		0·0665‡ ± 0·0088

* Mean ± standard error. † $P < 0{\cdot}02$. ‡ $P < 0{\cdot}01$.

became bound during 24 hr. to proteins in serum.

The results are summarized in Table 1. No significant change was observed in the weight of the thyroid during the period. The average epithelial cell height in the control group, however, was significantly increased compared with the pre-operation values. In the animals treated with morphine there was no histological activation, as values before and after the operation remained unchanged. The thyroidal uptake of iodine-131 in the treated group was lower than in the controls. The difference is statistically significant ($P<0\cdot01$). The ability of the thyroid to bind iodine-131 to proteins was similarly lowered. The levels of protein-bound iodine-131 in serum were significantly lower than in the controls ($P < 0\cdot01$).

The increased epithelial cell height in the control group suggests that the removal of half the thyroid tissue itself stimulates increased secretion of thyroid stimulating hormone. The administration of morphine prevented the morphological activation and markedly inhibited the thyroidal uptake of iodine-131 as well as the formation of hormonal iodine. Since all these functions of the thyroid are regulated by the thyroid stimulating hormone, it may be supposed that morphine is also able to block the secretion of the latter.

An Abnormal Type of Lymphocyte

DURING the past four years I have noticed in normally coloured smears of blood, bone marrow and spleen puncture from 9 cases of hepatosplenomegaly with strongly marked granulocytopenia and lymphocytosis, a considerable number of cells closely resembling lymphocytes but showing several special features. I have never observed this type of lymphocytes in lymphatic leukosis, which I have studied for many years from the cytological point of view, nor in any other disorder of the lymphatic system.

These cells prevailed in smears of bone marrow. In smears of spleen puncture there was a great mass of cells consisting almost exclusively of this type of lymphocytes.

Fig. 1 shows these cells in blood, bone marrow and spleen puncture. Their size corresponds to the size of a large lymphocyte. The nucleus, which is generally larger than the nucleus of an ordinary lymphocyte and usually central, is round, oblong or kidney-shaped. Sometimes there are two round or oblong nuclei partly covering each other. The nuclear membrane is sharply outlined. The chromatin is delicate and of a fine network, clearly differing from the compact masses of chromatin in normal lymphocytes. Sometimes, however, there are small chromatin blocks divided from each other by clear zones similar to the nuclear pattern of an ordinary lymphocyte. Sometimes there is a barely perceptible nucleolus corresponding in character and location to the nucleolus of a rather young lymphocyte. The amount of cytoplasm varies, it is bluish in colour, and meshy, usually fringed on the whole periphery. Sometimes, however, the amount is much reduced, as if used up, with only small shredded particles conserved around the nucleus. Occasionally azurophil granules closely resembling those of an ordinary lymphocyte can be seen.

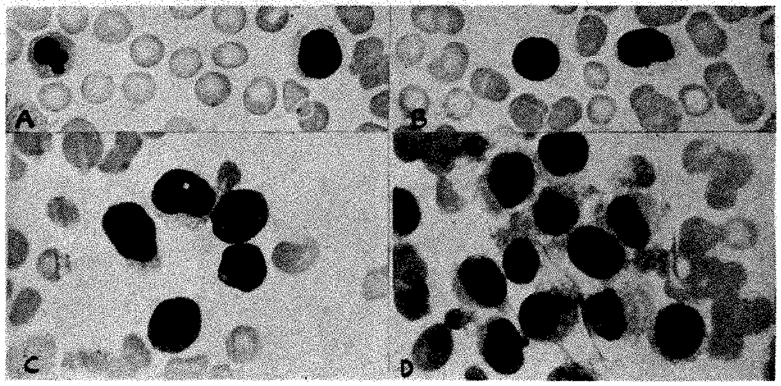

Fig. 1. *A*, Blood: a normoblast and abnormal lymphocyte with fringed cytoplasm *B*, blood: an abnormal lymphocyte with fringed cytoplasm and an ordinary lymphocyte *C*, bone marrow: abnormal lymphocytes with varying amounts of fringed cytoplasm *D*, spleen puncture: abnormal lymphocytes with fringed cytoplasm

At first I was not sure whether these cells, which show a negative peroxidase reaction and stain only faintly red with methyl green and pyronin, belonged to the series of lymphocytes or not. The phase-contrast microscope, however, revealed the same character and arrangement of mitochondria as in a mature lymphocyte.

In the first five cases, the clinical course was acute. All five findings at autopsy disclosed a rare type of tuberculosis known as "sepsis tuberculosa gravissima[1]", "areaktive generalisierte Tuberkulose[2]", or "septicémie tuberculeuse foudroyante maligne[3]". The remaining four patients are still under clinical control. The clinical course is acute in one case, subacute in one case, and chronic in the other two.

As a routine designation in the hæmograms I have called these lymphocytes 'Dozet cells', after the surname of the first patient in whom I noticed them.

So far I do not know whether this lymphocyte is characteristic of "sepsis tuberculosa gravissima". This question remains to be answered by further observation. Yet it is of interest to direct attention to this cellular element not only from the morphological point of view but also as a diagnostic difference with respect to lymphatic leukosis.

Significance of the Adrenal Glands during the Post-natal Development of Thermoregulation in the Rat

THE range of environmental temperature within which rats maintain a stable body temperature increases with age[1-3]. It is therefore possible that the lack of effect of adrenalectomy on thermoregulation before the sixteenth day after birth[4-6] is the result of the relatively very low environmental temperature used (5° C.) at which thermoregulation fails in very young rats. In order to test this hypothesis rats were adrenalectomized under cold anæsthesia on the fourth day after birth. One, two and three days after operation their power of thermoregulation was tested as follows: rectal temperature was taken with a thermocouple immediately before the experiment after removal of infant rats from the nest. The animals were then placed in a Bargeton–Krumm–Heller[3] respirometer and oxygen consumption was measured at an environmental temperature of 35° C. for 30 min. Then the external temperature was changed to 30° C. at which readings were continued for a further 60 min. Finally, the rectal temperature was again taken.

It was found that rectal temperatures of operated animals always dropped to significantly lower values than those of sham operated controls. Oxygen consumption always rose when the environmental temperature was lowered to 30° C. If cortisone was administered for three days between the fourth and seventh day after birth to adrenalectomized rats via the intramuscular route (0·5 mgm./ml. saline; 1 ml./100 gm. body-weight) the effect of adrenalectomy was nullified. Rectal temperatures no longer decrease to such an extent at 30° C. external temperature and oxygen consumption at 35° C. is increased. If control animals are treated in the same way oxygen consumption is increased significantly and rectal temperatures do not fall at all.

Thus on the third day after adrenalectomy the rectal temperature drops from 33·5 ± 0·481° to 31·9 ± 0·298°, while in similarly treated animals receiving cortisone the final temperature is 33·3 ± 0·466°. In control animals receiving cortisone rectal temperature remains at 34·6 ± 0·274°. Oxygen consumption in normal infant rats after treatment with cortisone is raised from 41 ± 3·33 to 60 ± 1·41 ml./100 gm./10 min. at 35° C. surrounding temperature and to even higher values at 30° C.

The above results show that the adrenal glands participate in the maintenance of body temperature in five-day-old rats. On the other hand, they evidently are not indispensable for the increase in oxygen consumption which occurs when the external temperature is changed from 35° to 30° C. The negative results obtained by previous workers[4-6] are probably due to the low environmental temperature used.

'Gastric Para-Mucus'

WHEN an aqueous solution of either iodoacetamide or N-ethyl maleimide, in suitable concentration, is applied topically to the mucosa of a canine Heidenhain pouch half an hour before the injection of histamine, the hydrochloric acid secretory activity of the pouch is inhibited completely, though reversibly[1]. This inhibitory action may be presumed to involve a competitive inhibition of one or more enzymes within the parietal cells, though Davenport's assumption[2] that these enzymes contain sulphydryl still awaits confirmation. Instead of the water-like solution of hydrochloric acid ordinarily obtained in response to histamine stimulation, the pouch now pours out a mucinous cell-free liquid of *p*H greater than 7, and sometimes even as high as ·8. Flow of this viscous liquid continues for many hours after drainage of the iodoacetamide or N-ethyl maleimide solution from the pouch, whereas the acid-secretory response to subcutaneously administered histamine usually lasts for no more than 1–1½ hr. Further evidence that this mucinous material bears no relation to the parietal secretion is given by the fact that the same response is obtained when the instillation of iodoacetamide or N-ethyl maleimide into the pouch is not followed by the subcutaneous administration of histamine.

This viscous fluid has the pale yellow or tawny appearance of blood plasma, even when it contains no visible blood, but its acid-neutralizing power, and its concentrations (after hydrolysis) of total solids, reducing substance, hexosamine, and total nitrogen are generally less than those for dog serum. Rather, these divers characteristics, together with its viscosity, suggest that we are dealing here with some kind of a mucinous secretion—different from the true gastric mucus obtained in response to topically applied acetylcholine[3], and certainly bearing no resemblance to the cellular variety of mucus formed in response to treatment of the pouch mucosa with eugenol[4]. It may be a modified form of mucus secretion proper, elaborated by the columnar epithelium of the mucosa, or it may be the hypothetical mucoid secretion of earlier investigators (sometimes identified with the dilution secretion or *Verdünnungssekretion*[5]); but as yet there is no sound evidence to support either such physiological characterization of this material. In view of this lack, and until such time as a definitive statement of its origin is possible, I propose to designate this fluid gastric 'para-mucus', because the Greek prefix (παρα) expresses (according to the Oxford English Dictionary) "faulty, irregular, improper, alteration, simulation, etc.".

About ten years ago, we reported from this laboratory that a 1 per cent aqueous suspension of mustard oil (allyl isothiocyanate) applied topically to the gastric mucosa, is a very poor mucigogue by comparison with irritants like an emulsion of clove oil, distilled water saturated with ethyl ether, etc., as evidenced by a persistently low viscosity, and probable small mucin content shown in metachromatically stained smears. Chemical analyses were not performed at that time. On the contrary, "the high volume, rate, and duration of secretion; the resemblance in colour of early specimens to blood plasma; the almost invariable appearance of fresh blood, increasing in intensity with progress of the experiment—all these, together with the observations on viscosity, opacity, etc., support the view that the 'secretion' is a transudate or exudate"[6].

It seems altogether possible that this material induced by mustard oil is essentially of the same nature as the gastric para-mucus evoked by iodoacetamide and N-ethyl maleimide, the presence of blood in the former being a result only of the great 'irritant' character of the allyl isothiocyanate in 1 per cent concentration. A fluid of similar appearance has been obtained from gastric pouches also following the topical application of 'Phenergan' (4 mgm./ml.) and, occasionally, 'Nupercaine'[7]. Whether these various mucinous fluids are identical with para-mucus obtained after the mucosa has been treated with iodoacetamide and N-ethyl maleimide can be decided only by chemical analysis. The results of electrophoretic, chromatographic and other chemical studies will be reported shortly.

This series of investigations was supported in part by a research grant (*C*–288) from the National Cancer Institute (National Institutes of Health), United States Public Health Service.

Distribution of Norepinephrine in the Heart

THE concentrations of norepinephrine found by various investigators in the hearts of different animal species are summarized in the 1956 monograph by von Euler[1]. These values range from 0·3 to 1·0 μgm. per gm. of heart tissue.

Recent reports, however, indicate that the heart norepinephrine-levels may be even higher than those found in the earlier experiments. Measurement of the levels in rabbit heart by a simple and sensitive spectrofluorometric method[2] gave an average value of 2 μgm. per gm., a considerably higher level than those reported earlier, but agreeing with the levels reported recently by Bertler, Carlsson and Rosengren[3]. Raab and Gigee[4] and von Euler[5] have reported levels of about 0·2 μgm. per gm. in dog heart. Levels in dog heart as measured by the spectrofluorometric technique[2], however, showed a concentration of about 2 μgm. per gm.

The high concentration of norepinephrine in heart brings up the question of its function in this organ. It was thought that study of the distribution of the amine in various parts of the heart might shed light on this question, since, to our knowledge, no distribution studies have been carried out on this organ.

Dogs of both sexes were killed by intravenous injection of pentobarbitone or by exsanguination. The hearts were removed immediately, dissected, and the various parts analysed for norepinephrine and epinephrine by the spectrofluorometric method described elsewhere[2].

Little epinephrine was found in any portion of the heart, the levels being less than 10 per cent of the norepinephrine concentration. Norepinephrine-levels are shown in Table 1. The average concentration in the atria was 2·7 μgm. per gm. It is noteworthy that the concentration in the portion of the right atrium which includes the sinoauricular node was not significantly different from that in other atrial samples. The level throughout the ventricular muscle was quite uniform—about 1·5 μgm. per gm. The endocardium may be devoid of norepinephrine since the valves, which are endocardial structures, lack norepinephrine. Furthermore, removal of endocardium and epicardium from ventricular samples did not significantly alter the levels found.

Table 1. DISTRIBUTION OF NOREPINEPHRINE IN NORMAL DOG HEART

Part of heart	No. of hearts	μgm. per gm.		
		Mean value of norepinephrine concentration	Standard error of mean	Range of values
Atria				
Atria, pooled	6	3·1	± 0·3	1·9–3·6
Right auricular appendage	4	2·4	± 0·4	1·9–3·5
Right atrium without appendage	2	2·7	± 1·0	1·7, 3·7
Portion containing sinoauricular node	4	2·3	± 0·5	0·8–3·1
Left auricular appendage	4	2·8	± 0·3	2·2–3·7
Left atrium without appendage	2	2·3	± 0·9	1·4, 3·2
	22 determinations			
(Mean of 22 determinations is 2·7 μgm. per gm.)				
Ventricles				
Apex of heart	11	1·3	± 0·2	0·7–2·9
Right ventricle	4	1·4	± 0·3	0·8–2·1
Right papillary muscles	4	1·5	± 0·3	0·7–2·2
Portion containing atrioventricular node	4	1·4	± 0·1	1·1–1·6
Left ventricle	4	1·3	± 0·1	1·1–1·6
Left ventricle, epicardium and endocardium removed	2	1·8	± 0·6	1·2, 2·4
Left papillary muscles	4	1·6	± 0·4	0·9–2·8
Septum	10	1·6	± 0·2	0·9–3·4
	43 determinations			
(Mean of 43 determinations is 1·5 μgm. per gm.)				
Valves of heart				
Semilunar valves	2	0	0	0
Mitral valve	2	0	0	0
Tricuspid valve	2	0·1	±0·1	0, 0·2
Major blood vessels				
Aortic arch	4	1·3	± 0·2	0·9–1·7
Pulmonary artery	3	1·1	± 0·3	0·8–1·6
Superior vena cava	1	0	—	0

The average norepinephrine concentration in the atria was significantly higher ($P < 0·001$) than in ventricles, the ratio being 1·8 : 1.

The concentrations of norepinephrine in the aortic arch and in the pulmonary artery were almost as high as in ventricular muscle, while the superior vena cava was apparently devoid of norepinephrine.

Since sympathetic denervation has been shown to reduce markedly the norepinephrine content of the heart[1], von Euler and other investigators concluded that the norepinephrine in the heart is associated with adrenergic nerve endings. Since stimulation of sympathetic nerves affects the heart-rate profoundly, it is perhaps not surprising that the atrial concentration of norepinephrine is significantly greater than the ventricular concentration.

Anatomical findings[6–8] and studies on the effect of electrical stimulation of sympathetic cardiac nerves on ventricular contractile force[9,10] suggest, however, that adrenergic nerve endings are distributed throughout the ventricles as well as the atria, a conclusion which is supported by the high concentrations of norepinephrine found throughout the ventricular muscle.

Polymorphism in the β-Globulins of Sheep

POLYMORPHISM in the β-globulins of cattle, giving five phenotypes[1,2], and in humans giving three phenotypes (Smithies, O., personal communication), has been described. The present communication concerns polymorphism in the β-globulins of the serum of sheep, giving to date eight phenotypes. The phenotypes are indicated diagrammatically in Fig. 1. The conditions for obtaining these serum protein differences by starch gel electrophoresis are similar to those described for cattle sera[1] except that 5–6 hr. is required to achieve adequate resolution of the β-globulins; in this time the trailing edge of the albumin zone migrates 6–7 cm.

It seems probable that the greatest degree of polymorphism in the serum proteins of mammals will be found in the β-globulins, notwithstanding the fact that serum protein polymorphism was first detected by Smithies in the haptoglobins of humans[3]. A rational nomenclature for the β-globulin phenotypes, sufficiently flexible to cover analogous systems in other animals, is therefore necessary. It is suggested that the proteins contributing to each β-globulin polymorphic system be designated by letters in sequence starting at the β-globulin nearest the albumin, that is, the one with greatest mobility; an intensely staining zone could be designated by a capital letter, a less intensely staining zone by a lower case letter, and the absence of the zone by omission of the letter. Such a phenotype nomenclature which makes no implications about the genotypes, is shown for the sheep β-globulin types in Fig. 1.

The distribution of the eight phenotypes in sheep found by examination of 118 abattoir samples (mixed breeds) was: 17 BcdE, 18 BcD, 13 BCd, 5 B, 2 bCdE, 45 bCD, 3 bCd and 15 cD.

The nature of the zones contributing to the one-dimensional starch gel electrophoretic patterns in sheep was determined by two-dimensional agar-starch gel electrophoresis as used for cattle[1] (Fig. 2).

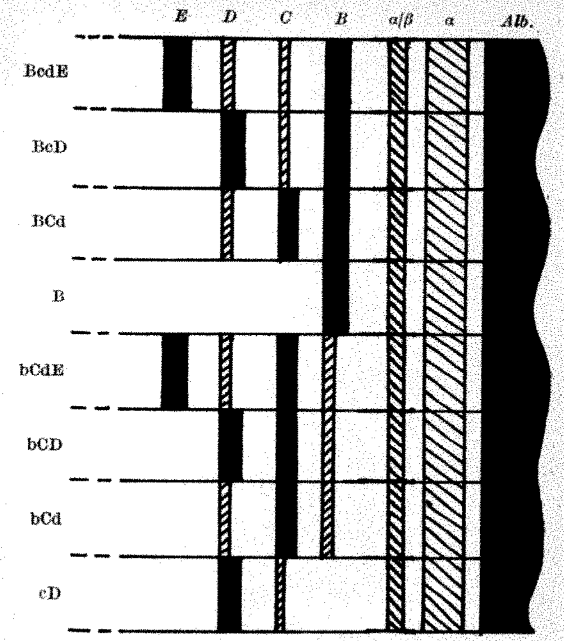

Fig. 1. Diagrammatic representation of β-globulin polymorphism in sheep sera by one-dimensional starch gel electrophoresis. Only a portion of the anodic side of the gel is shown. *B*, *C*, *D* and *E*, β-globulins; *α/β*, zone consisting of β-globulin *A* plus some α-globulin components; *α*, α-globulin components; *alb.*, part of albumin zone. Solid bands, intense staining; cross-hatched, medium or faint staining. For phenotype code, see text

It will be seen that the β-globulins coincide with some of the α-globulin components when the sera are run in starch gel only. Fortunately the α-globulins do not stain sufficiently intensely to obscure the β-globulin pattern, although where β-globulin *B* is absent, α-globulin zones 10 and 11 (Fig. 2) can be seen as background staining. Usually the α-globulin zone 9 (Fig. 2) can be seen as a faint poorly defined zone just behind β-globulin *E*. No 'thread proteins' such as those found in cattle[1] or pigs[4] were observed in sheep.

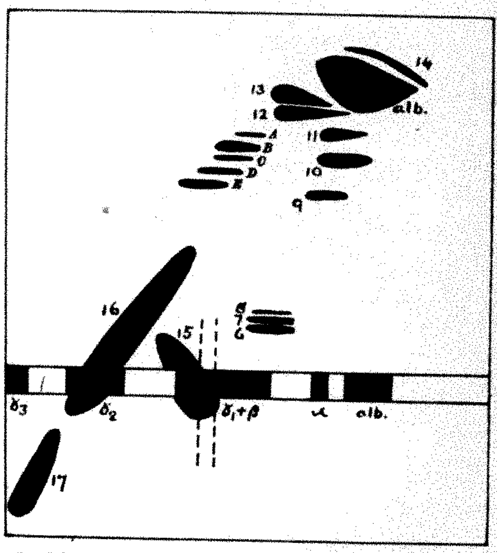

Fig. 2. Diagram prepared after two-dimensional agar/starch gel electrophoresis of type BcdE serum. Broken lines indicate position of original sample insertion in agar. *Alb.*, albumin; *α*, α-globulin (zones 9–13); *β*, β-globulin (zones *A*, *B*, *C*, *D*, *E*); γ_1, γ_2, γ_3, γ-globulins (zones 15, 16 and 17); zones 6, 7, 8, 'slow α-globulins'; zone 14, pre-albumin

So far insufficient mating data have been obtained to postulate genetic control, but it seems probable, by analogy with cattle and human results, that the various phenotypes will prove to be inherited.

Giant Compound Hair Follicles in the Skin of the Rabbit

THE hair of the rabbit grows from a compound follicle[1] which contains one large outercoat hair, a few smaller outercoat hairs of intermediate morphology and numerous fine undercoat hairs. The true compound nature of the follicle is best seen during the growth-phase, when the follicles extend into the dermis forming distinctive groups at their deepest level (Fig. 1). As the hair shafts reach the surface the compound follicle is subdivided by fibrous septa into smaller groups which surround the large outercoat hair. Each of these smaller groups of undercoat hairs penetrate the skin through a common follicle opening, whereas the outercoat hair has a separate opening.

If the hair is plucked out in the quiescent phase it can easily be separated into tufts that correspond to the pattern of the compound follicle (Fig. 2). This act of plucking out the hair initiates its regrowth cycle, and in the pigmented rabbit evidence of regeneration is first observed on about the seventh day, when the skin begins to darken as a result of the formation of pigment in developing follicles[2]. Between this period and the time the hair penetrates the skin on about the fourteenth day, the skin surface shows small discrete elevations uniformly distributed about 0·5–1·0 cm. apart (Fig. 3). Serial sections through the skin at this time show that these elevations are caused by giant compound follicles (Fig. 1) which contain several outercoat hairs and many more undercoat hairs than the normal follicle. In the chinchilla rabbit the central hair is large, thick and uniformly black in contrast to the banded black-and-white outercoat hair of the normal follicle.

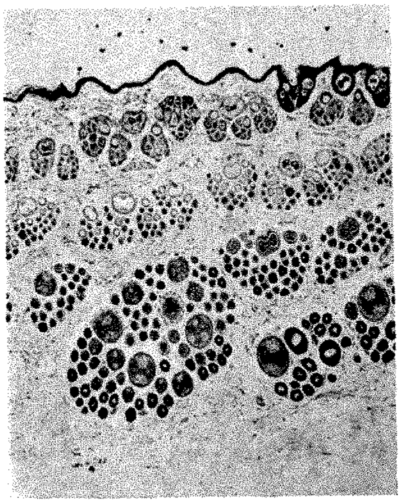

Fig. 1. Section, cut across the slope of the hair, of rabbit skin in the twelfth day of the regrowth cycle showing one giant follicle and several normal compound follicles. The subdivision of the follicle with the single isolated outercoat hair is seen as the hair shafts near the surface. (× *c.* 30)

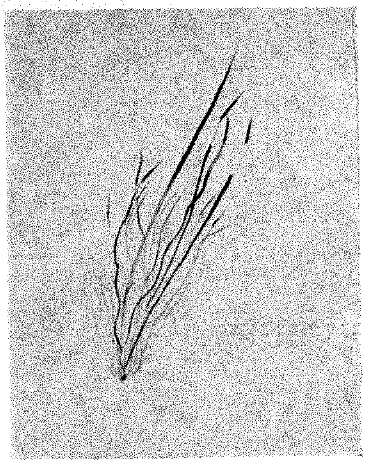

Fig. 2. Drawing of a tuft of rabbit hair showing the large black outercoat hair

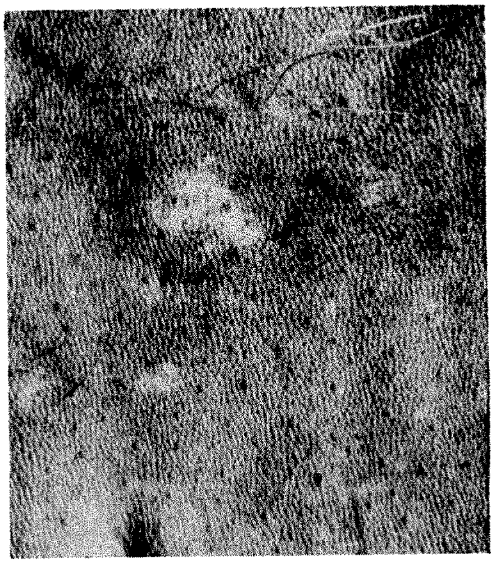

Fig. 3. Photograph of the skin of the rabbit on the twelfth day of the cycle showing nodular elevations caused by the giant follicles. (× 1½)

These giant follicles have always been seen in the chinchilla rabbit when the hair is regenerating, and observations indicate that they are present in many other types of rabbit, including the agouti, albino, rex and angora strains.

Capacitation of Mammalian Spermatozoa

It has been previously shown that spermatozoa of the rat and rabbit require to undergo some form of physiological preparation within the female reproductive tract before they are capable of fertilizing eggs[1]. This preparatory process, known as capacitation, has hitherto lacked more precise description.

Recently, we have obtained evidence that the acrosome is removed from the spermatozoon head before the entry of the spermatozoon into the egg. Modification and loss of the acrosome have been observed in living spermatozoa of the golden hamster, guinea pig and Libyan jird recovered in the fluid from the Fallopian tubes and in the cumulus oophorus. Further, spermatozoa found embedded in the zona pellucida of guinea pig and golden hamster eggs, lying free within the perivitelline space of golden hamster and jird eggs, and entering the vitellus of golden hamster and Chinese hamster eggs all lacked their acrosomes. In no instance was a spermatozoon that retained its acrosome found within any part of an egg. These and other observations indicate that, in the normal course of events, removal of the acrosome probably occurs at the surface of the zona pellucida.

Clearly the acrosome is not involved in the penetration of the egg, and its function is probably restricted to assisting the passage of the spermatozoon through the cumulus oophorus. Loss of the acrosome exposes a specialized region of the nuclear membrane, the perforatorium, and we believe that this is the organelle that enables the spermatozoon to make its way through the zona pellucida.

We therefore conclude that acrosome removal is a prerequisite of fertilization, and that the induction of those changes that lead to detachment of the acrosome represents capacitation.

A preliminary report of these investigations was presented at the ninth International Congress for Cell Biology, 1957; a detailed account is being submitted for publication elsewhere.

Effect of Gibberellic Acid on Fruit Set and Berry Enlargement in Seedless Grapes of *Vitis vinifera*

Although an increased set of fruit as a result of gibberellic acid or related compounds has been observed in tomatoes[1], there are insufficient data concerning the effect of this chemical on enlargement of fruit in any plant.

In several experiments performed at Davis, California, in 1957, an increase in fruit set and/or fruit size resulted from treatment with gibberellic acid. The potassium salt of gibberellic acid, supplied by Merck and Co., contained about 80 per cent active ingredient. 'Dreft' was used for a wetting agent. The procedure for determining average weight per berry, percentage of total soluble solids, and percentage of acid has been described previously[2].

Girdling (ringing) has long been used to induce fruit set and enlargement in Black Corinth grapes, although in recent years it has been partially replaced by applications of 4-chlorophenoxyacetic acid[3,4]. In one experiment flowering clusters on mature Black Corinth vines were dipped momentarily on May 31 into solutions containing gibberellic acid at 0, 1, 5, 20, 100 or 500 p.p.m., ten replicates per treatment. When the fruit was collected on July 30 the regulator at 1 p.p.m. had resulted in a fairly good set of large berries, but the clusters were straggly owing to occurrence of small undeveloped berries. The compound in the range 5–500 p.p.m. resulted in an excellent set of enlarged berries (Table 1). Heavier clusters and elongated berries resulted from higher concentrations of the compound. The percentage of total soluble solids was usually comparable even though the treated clusters were heavier. The regulator decreased the percentage of total acid.

Table 1. Effect of Gibberellic Acid on Yield and Composition of Black Corinth and Thompson Seedless Grapes

Treatment, concentration (p.p.m.)	Av. wt./ cluster (gm.)	Av. wt./ berry (gm.)	Total soluble solids (per cent)	Acid (per cent)
Black Corinth				
0 (not girdled)	91·6	0·26	23·4	1·75
1 (not girdled)	206·5	0·47	23·6	1·50
5 (not girdled)	258·0	0·58	23·9	1·29
20 (not girdled)	366·6	0·78	21·3	1·34
100 (not girdled)	391·3	0·99	23·0	1·26
500 (not girdled)	500·7	1·31	22·6	1·30
Thompson Seedless				
0 (not girdled)	0·66	1·59	22·4	0·79
5 (not girdled)	0·95	1·91	23·2	0·73
20 (not girdled)	1·46	2·71	18·9	0·83
50 (not girdled)	2·15	3·15	17·6	0·94
0 (girdled)	1·10	2·26	23·0	0·74

Girdling has been shown to increase size of berry in Thompson Seedless[2]. On June 11, after berry set was completed (berry shatter stage), mature, ungirdled Thompson Seedless vines were heavily sprayed with solutions containing gibberellic acid at 5, 20 and 50 p.p.m., four vines per treatment. One group of vines was ungirdled and unsprayed, and another girdled but unsprayed. Fruit was harvested on August 26. The weight of clusters and berries sprayed with the regulator at 5 p.p.m. was greater than those from unsprayed and ungirdled vines, but smaller than those from unsprayed but girdled vines (Table 1). Very large clusters and berries resulted from treatment with 20 and 50 p.p.m. The percentage of total soluble solids was lowest and percentage of acid highest in fruit sprayed with compound at 50 p.p.m., probably as a result of the greater weight of fruit in this treatment.

Elongation of stems and hastening of flowering, previously reported for other plants[1,5] occurred in grapes. Accelerated coloration in red grapes, and in ripening, occurred in many experiments not reported here.

It has been suggested that levels of naturally occurring auxins are of importance in fruit set and enlargement[6,7]. Perhaps naturally occurring gibberellic acid or related compounds may be concerned in fruit set and enlargement on grapes under discussion herein. Berry size of varieties with seeded berries was not increased appreciably. Perhaps seeds produce sufficient quantities of the compound to result in almost maximum berry enlargement. The occurrence of 'gibberellin-like' substances in many seeds[8] suggests an investigation be made on the regulator in grape seeds.

This work was supported in part by a grant from Merck and Co., Inc., Rahway, New Jersey.

Effects of Kinetin on Cell Division in *Paramecium caudatum*

Kinetin (6-furfurylaminopurine) has been reported to stimulate cell division in excised tobacco pith tissues[1], in onion root tips[2] and, most recently, in sarcoma tumour cells[3]. Lettré and Endo[4] found no changes in cell division or tumour growth with kinetin in cultures of normal or malignant human and animal cells. They concluded that these tissues either did not possess a kinetin-like trigger for cell division, or contained optimal levels of such a substance.

This communication presents some of the findings on changes in rates of division induced by kinetin in a free-living organism, *Paramecium caudatum*.

Stock cultures of *P. caudatum* (obtained from the Hebrew University Department of Zoology) were maintained as clones on hay infusion medium at 25° C. in the dark. Families were begun in depression slides containing a single animal in two drops of hay infusion plus four drops of sterilized tap water. Treatment slides contained hay infusion with kinetin (kindly supplied by Prof. F. Skoog), dissolved in sterilized tap water and added to the hay infusion at the time of treatment. All slides—treatments and controls—had equal proportions of infusion and water and were adjusted to pH 6·5–6·8.

The findings reported here were obtained from tests with isolation cultures using the following procedure. A single individual was isolated in a depression slide. After two divisions, the four resulting animals were transferred each to a new slide—one control and three different concentrations of kinetin solution. Thus each experimental observation was matched by its own control, originated from the same individual. The number of divisions per slide was recorded every 24 hr., after which two animals were transferred from each slide to new medium. Readings were made for three days in succession: at the end of these the experiment was discontinued and a new set begun. Mean division-rates of treatments and controls were compared and their differences tested for significance by Student's t test for the mean of differences.

Table 1. Comparisons of Division-Rates of *Paramecium caudatum* in Control Medium and in Various Concentrations of Kinetin

Concentration of kinetin (mgm./l.)	No. of 24-hr. period comparisons	Mean No. of divisions/24 hr.		Proportion $\bar{e}/\bar{c}$	$t\bar{c} - \bar{e}$
		Control $\bar{c}$	Kinetin $\bar{e}$		
0·25	60	1·32	1·48	1·12	−1·57
0·5	18	1·24	1·72	1·39	−2·71*

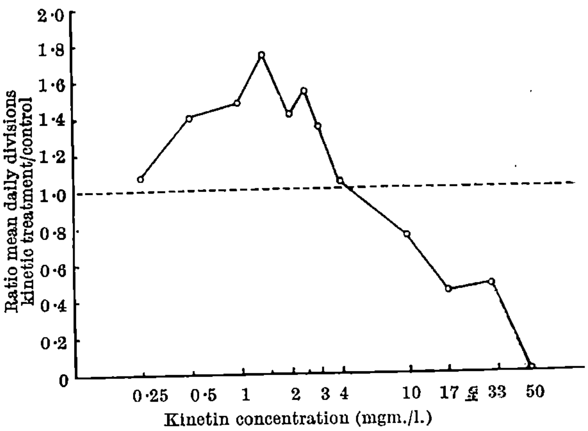

Fig. 1. Variations in division-rate of *P. caudatum* with changing kinetin concentration

In order to test a possible effect of the kinetin on the bacterial populations of the culture media during the 24-hr. periods, hay infusion samples—with and without kinetin—were tested on agar and in bouillon. No gross changes were observed in either size or constitution of the bacterial populations.

Table 1 shows appreciable changes in mean daily division frequencies (for 3-day periods) in cultures containing a variety of concentrations of kinetin. 100 mgm./l. kinetin caused death of all *Paramecia* within ½ hr., while 50 mgm./l. blocked division completely without being lethal. (The animal remained alive during the 3-day period but did not divide.) Between 33 mgm./l. and 0·25 mgm./l. we found a sensitive range of responses from significant elevations to severe inhibition of cell multiplication (Fig. 1). As the dose of kinetin decreased from 33 to 4 mgm./l., the ratio of experimental to control divisions rose from 0·44 to approximately 1. The ratio rose steadily above 1 as the concentration dropped from 4 to 1·5 mgm./l., and fell steadily back to 1 as the concentration dropped from 1·5 to 0·25. It is interesting to note that the concentrations found to be most active in our material, as well as in onion and tumour cells[2,3], have all been of the same order of magnitude.

Tests are under way to determine the time of onset of the effect of kinetin during the life-cycle of the protozoan cell.

We are indebted to Miss Edna Naim, Mr. Y. Ginzburg, Mr. Y. Koffler and Prof. L. Guttman for their assistance and advice during various phases of the investigation.

These studies were supported, in part, by the Anna Fuller Fund.

Chromosomes and Chromocentres in the Nuclei of *Halidrys siliquosa* (L.) Lyngb.

DIVIDING nuclei in the apical groove of *Halidrys siliquosa* show large numbers of small chromosomes, and at metaphase more than 55 have been counted (Fig. 1*c*, *d*, *e*). Metaphase plates at the first three divisions in developing antheridia have given counts of the order of 30 chromosomes (Fig. 1*b*), and one at the first division of the oogonium of approximately 28 chromosomes. This indicates that the thallus of *H. siliquosa* is diploid with meiosis at the first division of the gametangia, as is usual in the Fucales[1].

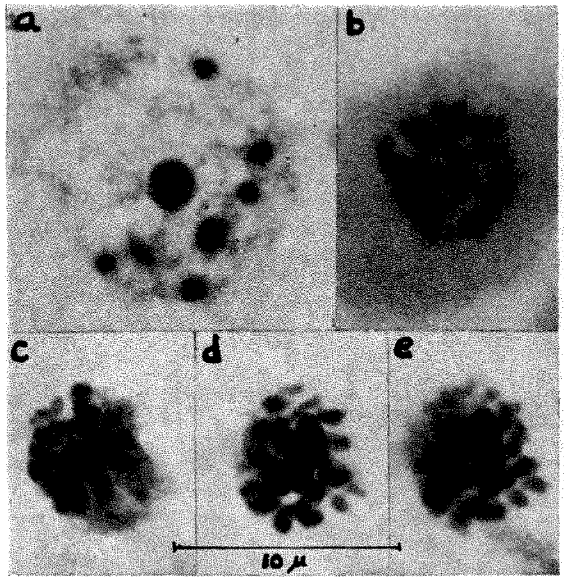

Fig. 1. Photomicrographs of nuclei of *Halidrys siliquosa*, all to the same scale. *a*, Acetocarmine smear of a nucleus of a medullary cell showing the nucleolus and seven chromocentres; *b*, Feulgen-stained metaphase plate at the first division of the antheridial initial: this plate gave a count of 34; *c*, *d*, *e*, three optical planes of a metaphase plate of a dividing meristoderm cell in the apical groove. This plate gave a count of 55 chromosomes plus several more the number of which could not be accurately determined, lying in a higher plane. The illustration was prepared by W. H. Smithson from untouched negatives

The resting nuclei of *H. siliquosa* contain several Feulgen-positive granules about 1μ in diameter (Fig. 1*a*) and slightly larger than the chromosomes, as has been described by le Touzé[2] and Roy[3]. The number of granules varies from cell to cell but is usually between 2 and 9, whether the cell is diploid, as in the somatic cells, or haploid, as in the developing gametangia. Such variability in number and independence of chromosome complement is a characteristic of chromocentres[4]. It seems possible that the eight chromosomes recorded by Moss and Elliot[1] in both somatic and reproductive cells of *H. siliquosa* correspond to these bodies, which are probably chromocentres.

A more detailed account of this work will appear elsewhere[5].

Cytology of Indian Species of *Artemesia*

CONSIDERABLE cytological work has been done on the genus *Artemesia* in North America[1,2], Japan[3] and Europe (cf. Darlington and Wylie[4]); but so far nothing has been known about the Indian species. The genus, besides being of medicinal importance, is extremely interesting from the cytotaxonomic and cytogeographic points of view. It was therefore thought worth while to work out the available species of the genus. Following the conventional taxonomic treatment we have worked out 11 species out of 27 reported by Hooker[5] from the Indian subcontinent. In the present investigation the various species have been primarily sampled from the north-western Himalayas; but material from the eastern Himalayas and other areas has also been studied. This has been supplemented with the study of herbarium specimens. Most of the species have been worked out for the first time. In addition to the 11 Indian species, the chromosome number in *A. vulgaris* Linn. from Germany has also been investigated. The chromosome numbers are given in Table 1.

Table 1

Species	Chromosome No.	
	n	2*n*
A. scoparia Waldst. and Kit.	8	16
A. absinthium Linn.	9	—
A. glauca Pall.	18	36
A. laciniata Willd.	—	18
A. maritima Linn. (Kashmir)	18	—
A. maritima Linn. (Japan)	27	—
A. parviflora Roxb.	9	18
A. roxburghiana Bess.	9	18
A. roxburghiana Bess.	18	36
A. tournefortiana Reichb.	9	18
A. vestita Wall.	9	18
A. vulgaris Linn. (Germany)	—	16
A. vulgaris Linn. (India)	18	—
A. vulgaris Linn. (India)	27	54
A. species	9	—

One of the interesting aspects of this study is the cytological situation in Indian *A. vulgaris*. In this connexion, it is pertinent to mention that *A. vulgaris* Linn. was originally described from northern Europe[6]. The chromosome number of this species ($2n = 18$) was worked out by Weinedel as early as 1928 (cf. Darlington and Wylie[4]). In view of all the subsequent work it is reasonable to revise the above number to $2n = 16$ [1,7-10]. This is fully borne out by the present investigation since we also found 16 chromosomes in root-tips from seeds collected at Kitzeberg near Kiel (Germany) and sent to us by Prof. H. D. Wulff. This is a significant point, since Indian *A. vulgaris* has been compounded from the basic number 9 and not 8 as expected on the basis of true *A. vulgaris* from Europe. Evidently the former taxon has to be appropriately evaluated taxonomically.

The Indian *A. vulgaris* complex is also interesting phytogeographically. We have found only diploids in the innermost Himalayas, in regions which have undergone a period of glaciation, and often at such places glaciers are still in existence. In the middle Himalayas diploids are at the tops of mountains and perhaps extend farther down. The tetraploid forms occur only at lower altitudes and extend also into the valleys below. In the outer Himalayas the diploids of this complex are either rare or have not been found so far, whereas tetraploid forms are preponderant. The hexaploid forms appear at lower altitudes and have also been found in valleys between the outer Himalayan foothills and the Siwalik Ranges. Furthermore, hexaploid has also moved down to the Nilgiri Hills (south India) in all probability through Mount Abu. From a study of the herbarium specimens we have reason to believe that hexaploid *A. vulgaris* also occurs in Ceylon, and on the eastern side it has also moved down to the Martaban Mountains in Burma. This is an interesting situation and will be further elaborated later.

A. maritima Linn. is a widespread species. It is distributed from the coasts of Europe and extends throughout saline tracts in north Asia[5]. The species has been reported as diploid from Europe[11] and as hexaploid from Japan[3]. We have confirmed the later report from plants at Yarikhah Drug Farm (Tangmarg, Kashmir) which were raised from seeds imported from Japan. We have, however, found the indigenous plants of the species at Gurez (Kashmir) to be tetraploid.

Fuller discussion will be published elsewhere.

We are grateful to Col. R. N. Chopra and Dr. I. Chopra (D.R.L., Jammu) and Prof. P. N. Mehra (Panjab University) for their encouragement and for affording us facilities to carry on this investigation. Furthermore, we are indebted to Prof. H. D. Wulff (Saarbrucken, Germany) for sending seeds of European *A. vulgaris*.

Chromosome Size in *Lolium temulentum* and *L. perenne*

Morphologically the grasses *Lolium perenne* and *L. temulentum* are markedly dissimilar and easily distinguished from one another. They differ also in habit and in their breeding system; the former is perennial and outbreeding, while the latter is an annual and inbreeding. Despite their divergencies in form and habit, the species can, however, be crossed, and hybrid plants are readily grown from seed produced when *L. perenne* is used as female parent. This was demonstrated by Jenkin[1], who has described the hybrids in detail.

A cytological investigation by Thomas[2] has revealed considerable genetic variation in the size of chromosomes. When the chromosomes were compared in order of size, those of *L. temulentum* were found to be approximately a third longer than those of *L. perenne*. In seeking to explain this variation there are two possibilities to consider. Either there are differences in the amount of genetic material in the chromosomes of the two species or there are genotypic differences between them which affect chromosome size—such as reported between a number of species[3], and even between individuals within a species[4]. Comparisons were therefore made between the parent species and their hybrids to decide which of these possible causes applies in this instance. This was done by comparing the lengths of particular chromosomes in the nuclei of the parent species with their lengths in hybrid nuclei. The measurements were made in sectioned preparations of root tips which had not been subjected to pre-treatment of any kind that would affect the length of chromosomes.

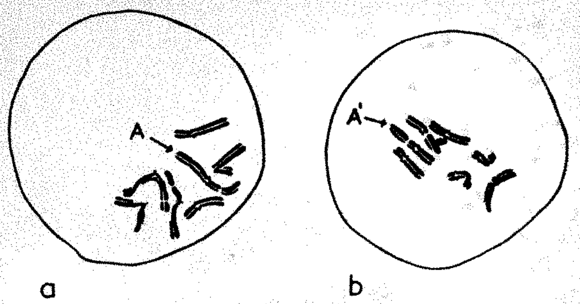

Fig. 1. The first pollen grain mitosis in (*a*) *Lolium temulentum* and (*b*) *L. perenne*. The average chromosome length is about a third greater in *L. temulentum*. (× 1,000)

In *L. temulentum* the chromosomes are too long to permit accurate measurement of complete nuclei. Consequently, one particular chromosome in the complement, *A* (Fig. 1*a*), was measured in suitable cells in the parent plants and in the hybrids. Similar measurements were made of the *L. perenne* chromosome, *A′* (Fig. 1*b*). The chromosomes were identified by the positions of their centromeres and secondary constrictions. Their lengths relative to one another are typical of the average length ratio between the chromosome complements of the two species. Whether they are homologous is not certain, but, from their appearance, probable. Sample measurements from within species were homogeneous, so also were those within hybrids. The results, therefore, were pooled and are represented in Fig. 2.

The average length of each chromosome within cells of the parent species is not significantly different from that in the cells of the hybrid, and the ratio A/A' calculated from measurements in the parent cells (1·3) is much the same as the ratio calculated from hybrid cells (1·4). There is, therefore, no evidence that the size difference is to any extent genotypically determined. The difference, we conclude, is at least mainly due to additional genetic material in the chromosomes of the inbreeding species.

This interpretation is corroborated by our own and Thomas's observations of meiosis in the pollen mother

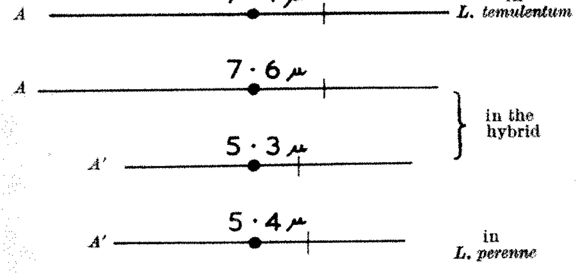

Fig. 2. The average lengths of a chromosome from each species in the nuclei of the parent cells and in those of the hybrid cells. The lengths are based on ten measurements in each case. Lengths of the secondary constrictions are not given

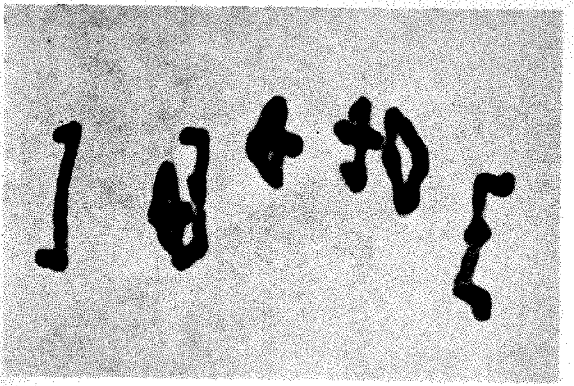

Fig. 3. First meiotic metaphase in a pollen mother cell of the *Lolium* hybrid showing asymmetrical bivalents. (× 1,750)

cells of the hybrids. At pachytene unpaired loops indicating deficiency or excess of genetic material are frequent. At metaphase the persisting inequality of chromosome size is manifested by the distinct asymmetry of up to six of the bivalents (Fig. 3). These asymmetrical bivalents are, with respect to long and short arms, orientated at random. There is no evidence for 'affinity'.

There may well be a causal relation between the variation in the amount of genetic material in the two species and the difference in their breeding systems. We have no evidence to show whether this is so, or how it may operate.

We wish to thank Mr. Beddows, of the Welsh Plant Breeding Station, Aberystwyth, for seeds of *L. temulentum*.

Fortifying Influences of Coconut Milk and Cow's Urine on 2,4-Dichlorophenoxyacetic Acid in the Control of Button Shedding in the Coconut

DURING several trials carried out by us with different hormones in the control of button shedding in the coconut, there was clear indication that, while sprays of 2,4-dichlorophenoxyacetic acid in 30 p.p.m. strength helped in securing a heavy set of buttons, quite a large number of them turned out to be abnormal or barren and markedly reduced in size when they attained maturity. This was observed to be particularly pronounced when pre-fertilization sprays were given. Although a change from pre-fertilization to post-fertilization sprays brought about a considerable reduction in the occurrence of abnormal and barren nuts and an appreciable improvement in the size of nuts at maturity, it did not help in completely offsetting the defects. It was therefore thought worth while to test the utility of coconut milk and cow's urine in overcoming these defects, since these might, by virtue of their growth-promoting properties, be expected to fortify the action of 2,4-dichlorophenoxyacetic acid, acting synergistically[1] or in some other way.

Preliminary trials were accordingly undertaken by using mixtures of coconut milk or cow's urine (which by themselves were inactive in improving button setting) with equal volumes of 2,4-dichlorophenoxyacetic acid in order to ascertain to what extent these would serve as an improvement. The results of these trials have indicated the interesting beneficial effect in using the mixtures, as these have not only helped to increase the percentage set of nuts and their overall development, but also reduced the incidence of barren nuts compared with the results secured with sprays of 2,4-dichlorophenoxyacetic acid alone, as may be seen from the results presented in Table 1.

Table 1

Characters determined	Control (water spray)	Sprays of 2,4-D alone	Sprays of 2,4-D mixed with coconut milk	Sprays of 2,4-D mixed with cow's urine
Mean percentage set of good nuts	7·62	26·20	44·83	31·23
Mean No. of under developed nuts	0·00	9·66	4·33	4·66
Mean vol. per nut (ml.)	2,158·33	1,516·67	2,373·33	2,360·83
Mean wt. per nut (gm.)	903·33	619·00	745·40	731·00
Mean wt. of copra per nut (gm.)	171·67	135·00	152·50	150·33

2,4-D = 2,4-dichlorophenoxyacetic acid

It is quite clear that there is a significant fortifying influence when 2,4-dichlorophenoxyacetic acid was used with a supplement of coconut milk or cow's urine and that the former proved to be superior in its synergistic effect than the latter.

Further trials are in progress to evaluate the beneficial effects of these and similar other mixtures on a statistical basis. We thank Dr. K. P. V. Menon for his interest in the work and Mr. T. P. Gopalakrishnan for his technical assistance.

An Infectious Fertility Factor for *Pseudomonas aeruginosa*

ONE unusual feature of the system of sexual recombination occurring in *Escherichia coli* is the infectious nature of the *F* factor. *F* − strains may be readily converted to *F* + by growing the two types together[1,2].

A similar type of sexual recombination to that occurring in *E. coli* occurs in *Pseudomonas aeruginosa*[3,4]. Two of the *Pseudomonas* strains used, 1 and *L*, are interfertile. Furthermore, 1 is self-sterile but *L* is self-fertile with a lower frequency of recombination than the 1 × *L* combination. This situation is comparable to the fertility system occurring in *E. coli K*12. Strain 1 is the equivalent of the *F* − strain, strain *L* the equivalent of the *F* +. Previous attempts to find an infectious fertility factor in *Pseudomonas* have, however, been unsuccessful. In those experiments, strain 1 and strain *L* auxotrophs were grown together under various conditions and the strain 1 auxotroph afterwards re-isolated. However, in no case were the mating characteristics of strain 1 altered in any way.

It has been previously shown that from crosses of multiple auxotrophic strains of 1 and *L*, auxotrophic recombinants may be isolated which show segregation for the ability to cross with either strain 1 or *L*[3]. Most of the recombinants resemble strain 1 in many of their characteristics, for example, pigment formation and susceptibility to phages. Thus it was thought possible that those recombinants of *L*-like mating ability may show a greater ability to transfer a fertility factor, should it exist.

A doubly auxotrophic recombinant $R629$ (IV$_1^-$ T_1^- S^s), *iso*leucine plus valine requiring, tryptophan requiring, streptomycin sensitive and *L* mating type, was obtained from the cross $1(M_1^- T_1^-)$, methionine requiring, tryptophan requiring, × $L(Ad^-$ IV$_1^-)$, adenine requiring, *iso*leucine plus valine requiring. This recombinant was mixed with a strain 1 auxotroph, $1(T_1^- S^r)$, tryptophan requiring and resistant to streptomycin, in 'Difco' nutrient broth plus 0·5 per cent 'Difco' yeast extract in a ratio of 20 : 1 in favour of $R629$ and grown overnight on a shaker at 37° C. The mixture was plated out on 'Difco' nutrient agar plus 250 µgm./ml. streptomycin to re-isolate the strain 1 auxotroph. Twenty-five colonies of this strain were then picked off and tested to see if overnight growth in the presence of the *L* mating type $R629$ had caused any change in the mating type of $1(T_1^- S^r)$, that is, the ability to cross with either strain 1 or strain *L*. It was found that 20 of the 25 colonies picked had permanently acquired the ability to cross to strain 1, thus resembling strain *L* in their mating ability. This change is analogous to the infection of $F-$ strains in *E. coli K*12 to become $F+$. The conclusion is drawn that a factor similar to the *F* factor in *E. coli K*12 controls fertility in the 1 and *L* strains. This factor has been named *FP*. Thus, strain 1 is $FP-$ and strains *L* and $R629$ are both $FP+$.

No reason can be given at present for the failure of strain *L* to infect strain 1 with *FP*. The infectivity of *FP* within strain 1 is irregular. Infection of a $1(FP-)$ strain from a $1(FP+)$ strain under the above conditions occurs only at low frequency and it is possible that the optimum conditions of transfer have not been obtained. The change from $FP-$ to $FP+$ has been achieved in a number of different strain 1 auxotrophs. Different lines derived from strain 1 vary in the facility with which they are converted from $FP-$ to $FP+$, and one of these lines has proved refractory to this change. It is thought possible that the transfer of *FP* may be under the control of certain hereditary factors. These factors may be also responsible for the segregation of *FP* in recombinant progeny previously observed.

In view of recent experiments[5] on the effect of acriflavine on the conversion of $F+$ to $F-$ in *E. coli K*12, the action of this substance on *FP* was investigated. No conversion of $FP+$ to $FP-$ could be accomplished either by growing the $FP+$ strains in 'Difco' nutrient broth plus 200 µgm./ml. acriflavine for up to 48 hr., or by making $FP+$ strains resistant to 1 mgm./ml. acriflavine.

Attempts were also made to select $FP-$ mutants from $FP+$ strains by selection for mutants with higher motility[6]. Repeated trials failed to produce any $FP-$ mutants by this method.

We wish to thank Prof. S. D. Rubbo for his interest in this work.

Acetylcholine in Milk

ACETYLCHOLINE has recently been reported to be present in low concentrations (0·1–1 µgm./ml.) in the milk of various species[1–4]. On the other hand, the mammary gland does not appear to possess a cholinergic innervation[5,6]. Accordingly, the question of the presence of acetylcholine in milk has been re-examined.

Fresh cows' milk, assayed on the frog rectus abdominis muscle preparation, gave varying responses equivalent to 0·1–0·4 µgm. acetylcholine chloride/ml. The activity differed from that of acetylcholine in the following ways: (1) the dose-response curve was much steeper; (2) heating the milk at *p*H 12 and 100° C. for 10 min. (conditions which destroy acetylcholine) caused little or no reduction of the activity; (3) amounts of milk which should have evoked, on the basis of their acetylcholine equivalence on the rectus, a good response from the anti-histamine-treated guinea pig ileum, failed to do so; (4) samples of milk, ashed and dissolved in a volume of water equal to that of the original sample, showed the same activity as the original milk. This suggested that the rectus activity was due to an inorganic constituent of the milk, probably potassium. It was found possible to duplicate the response to the milk with a potassium chloride solution of the same potassium content.

Since acetylcholine might be present in milk in a bound or pharmacologically unavailable form, or in such low concentration as to escape detection unless concentrated, the milk was treated with trichloracetic acid and the basic constituents of the trichloracetic acid supernatant precipitated as reineckates, procedures which release and concentrate acetylcholine from tissues (see ref. 7 for references). The trichloracetic acid was added to a final concentration of 10 per cent (w/v); the precipitate was removed by centrifugation, extracted with 10 per cent (w/v) aqueous trichloracetic acid and again removed by centrifuging. The combined supernatants (trichloracetic acid extract) were extracted with ether to *p*H 4·5 to remove the trichloracetic acid and the ether removed in a stream of air before testing. Bases were precipitated as reineckates by the addition of excess saturated ammonium reineckate and converted to the chlorides by passing the reineckates in 50 per cent (v/v) aqueous acetone through a column of the anion exchanger 'Deacidite *FF*' (Permutit Co., Ltd., London, −16 +50 mesh) in the chloride form. Control experiments with acetylcholine gave an overall recovery of about 50 per cent for this procedure. Potassium and choline were estimated in the various fractions by flame photometry and by the enneaiodide method[8] respectively.

The activity of the various fractions on the rectus was, in every case, alkali-stable and could be equated with a solution of potassium and choline of equivalent strength. Whereas the activity of the original milk was almost entirely due to potassium, the activity of the base concentrate was mainly due to choline; that of other fractions was due to both substances. On the ileum, about 80 per cent of the activity of the base concentrate was abolished by the anti-histaminic pyrilamine maleate (1 μgm./ml.), and was attributed to histamine; the remaining 20 per cent was more than accounted for by the choline content of the concentrate.

The conclusion drawn from these experiments is that the acetylcholine content of milk is negligible, and that the contractions of the frog rectus and guinea pig ileum preparations produced by milk or milk extracts are due to the potassium, choline and histamine content of milk.

The skilled technical assistance of Miss J. M. Gilson is gratefully acknowledged.

Use of Tidal Streams by Migrating Elvers (*Anguilla vulgaris* Turt.)

Each spring large numbers of elvers enter the Dutch Wadden Sea through the Marsdiep tidal inlet and migrate to the places where freshwater is discharged, such as at the sluices in the enclosing dam of the Ijssel Lake at Kornwerderzand and Den Oever (Fig. 1).

To study the migration in this tidal area, catches were made in the Texelstroom and the Marsdiep with a 1 m.^{2} ring-trawl during the years 1955, 1956 and 1957, using a small cutter. The catches consisted of horizontal surface hauls of ¾ hr. each, mostly made at night, during the flood as well as during the ebb. During both tides they were carried out alternately in the direction of the North Sea and in the direction of the inland waters, the speed of the boat being approximately constant in relation to the flowing water.

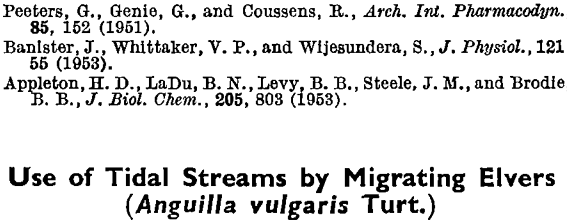

Fig. 1

If the elvers, which rise to the surface at night, do indeed swim actively from the North Sea to the freshwater, we would expect a greater yield of the hauls made towards the North Sea than of those made in the opposite direction. Actually, however, no significant differences in yield between hauls in either direction were found. This seems to exclude the possibility of an active migration of elvers swimming towards the freshwater.

A very significant difference was found, however, between the catches made during the flood tide and the ebb tide, respectively. Three to ten times more elvers were caught during the flood. This means that the greater part of the animals leave the surface during the ebb.

Therefore, during the spring of 1957, catches were also made at a depth of 8 metres, at places where the total depth was 10–20 metres. Also at this depth the yields were much larger during the flood than during the ebb. Hence, we must suppose that during the ebb tide the elvers are to be found near or on the bottom.

It follows from these observations that the elvers most probably use the tidal streams for their migration; they are transported in the direction of the inland waters by the flood, and go to the bottom during the ebb in order not to be carried back to sea.

By fishing in the day-time we obtained evidence that in daylight also this method of migration is used; however, the elvers do not reach the surface then. We have not yet established whether during the ebb the elvers dig themselves into the sand or swim against the current close to the bottom.

The migration principle described above is in accordance with a hypothesis developed theoretically by Van Heusden[1], who also assumed a phase of pelagic transport of the elvers by the flood tide and a phase of active swimming close to the bottom against the ebb tide.

On the other hand, Deelder[2] found no conclusive differences between ebb and flood catches from a ship anchored fairly near the sluices (Wierbalg, Visjagersgaatje) in the years 1947–50. The discrepancy between his and our results, however, can probably be explained as follows.

From our observations in 1957 it was established that the great majority of the elvers passed the Marsdiep during the end of February and the beginning of March. From the observations kindly put at our disposal by the Dienst van de Zuiderzeewerken, we learned that the elvers arrived a full month later at the sluices of Den Oever. Hence, there must be an area between the Marsdiep and Den Oever where the migration suffered a temporary delay; in this area an important accumulation of elvers should take place. Catches made in the Wierbalg during the period in question indeed gave yields which exceeded those in the Marsdiep and the Texelstroom by approximately a hundred times. Moreover, the yields of the ebb and flood catches did not differ significantly. We assume, therefore, that Deelder's results refer to catches made in an area where the migration has temporarily come to a standstill.

The assumption of a temporary stagnation of elver migration in front of the freshwater outlets is also in accordance with the observation of Deelder[3] that at the sluices of Den Oever the elvers at the beginning of the season do not show any preference for freshwater, whereas after some time they are strongly attracted by it.

As regards the use of tidal streams by the elvers migrating from the open sea to the area of stagnation, an important problem arises. How do they discriminate between the flood and the ebb ?

Van Heusden[1] supposed that differences in salinity play an important part. One could imagine, for example, that the elvers remain on or near the bottom so long as the stream (mostly the ebb[4]) carries water of lower salinity, whereas they leave the bottom as soon as the stream (mostly the flood[4]) provides water with a higher salinity. Our observations have not progressed sufficiently to allow a conclusion in this respect ; probably also the water temperature exerts a certain influence.

This investigation is supported by a grant from the Netherlands Organization for Pure Research (Z.W.O.).

Relationship between Aggressiveness and Egg Production in the Domestic Hen

A relationship between position in the peck order and egg production in the hen was first reported by Sanctuary[1] (quoted by Guhl[2]), who found that the birds in the upper half of the peck order laid more eggs than those composing the lower social level. This observation was confirmed by Guhl[2], who obtained a correlation of 0·26 (P, 0·01) between the number of birds pecked in the peck order and the number of eggs laid by 96 White Rock pullets.

The following observations were made on an Australorp flock maintained on the Animal Husbandry Farm of the University of Queensland. The experiment involved the measurement of aggressiveness of pullets in two groups, the first in battery laying cages and the second in an intensive shed on deep litter.

All birds were scored against panels of 10 birds under standard conditions[3] ; 6 such panels were used.

There seemed to be no relationship between aggressiveness score and egg production for birds housed in laying cages and, while there appeared to be some effect of aggressiveness on egg productivity in intensively housed birds, it did not appear to be linear. It seems that the majority of birds with low egg production also have low aggressiveness scores. This can similarly be discerned by inspection of Guhl's[2] scatter diagram.

Since Collias[4] has reported that position in the peck order is one of the factors which makes for success in single encounters of the type used in scoring aggressiveness, and correlations between scores and peck order position in assembled groups of these birds have been demonstrated, it would appear that the low aggressiveness scores are reflecting low peck order position in the intensively housed birds. Low position in the peck order is related to low priority at the feed troughs, nests and roosting places[5], and it would appear that it is the rather harsh environmental conditions to which these birds are subjected that is responsible for their low egg production and thus for the observed correlation.

Blyth[6] considered the shape of the egg production frequency distribution to be fundamentally normal although in fact it is skewed with a long 'tail' towards zero. She considered this to be the result of factors not specifically concerned with egg production. The frequency distribution for egg production of sisters housed under three environments, caged, semi-intensive and intensively on deep litter, shows an increasing degree of negative skew from cage to intensive. This suggests that position in the peck order is certainly one of these factors, though the fact that the 'tail' is still present in the caged birds suggests that it is not the only factor. Recent work[7] involving the feeding of antibiotic and vitamin B_{12} supplements has been effective in raising the egg production of low-producing birds while apparently leaving the high-producing birds unaffected. This suggests that this treatment has been effective in removing even more of the 'tail' from the distribution.

Sodium Phosphate Crystals on Salt Fish

Several times in the past few years, samples of undried or partly dried salt cod with an accumulation of crystals appearing over the surface have been submitted to this laboratory for examination. These deposits did not resemble either the sodium chloride or the calcium sulphate crystals often found on salt fish. One sample had many water-clear rhombic crystals with edges 2 cm. or more long. Others had a second type of crystals : they were dry, powdery white, and thickly scattered over the surface. Curiously, chemical analysis indicated that both types of crystals contained large proportions of phosphate and sodium, a small amount of chloride, but no sulphate, calcium or magnesium.

When the clear rhombic crystals were exposed to the dry laboratory atmosphere for a day, they changed into a white powder, similar to the second type. This powder contained 20·0 per cent moisture and appeared to be the dihydrate of disodium hydrogen phosphate. On analysis of the sample dried at 105° C., the sodium, phosphate and chloride contents indicated 96·0 per cent disodium hydrogen phosphate with 3·0 per cent sodium chloride.

Thus, the clear rhombic crystals appear to have been the dodecahydrate, the least soluble of the sodium phosphates, which in a dry atmosphere loses water to form the dihydrate (containing 20·2 per cent water) in a white powdery form. This is the form found in samples of the second type.

Since sufficient observations on the solubility of disodium hydrogen phosphate in a solution saturated with sodium chloride were not available, determinations were made at temperatures varying from 0° to 20° C. The results, with some values taken from the literature[1,2], are given in Table 1, and in Figs. 1 and 2.

Table 1

Temperature (° C.)	System $Na_2HPO_4.12H_2O$–NaCl–H_2O Solubilities (gm./100 gm. H_2O)						System $Na_2HPO_4.12H_2O$–H_2O Solubilities (gm./100 gm. H_2O)

Values *A*, equilibrium approached from higher temperatures; values *B*, equilibrium approached from lower temperatures

Fishery salt contains only traces of phosphate. On the other hand, and in agreement with other results[3,4], fresh cod muscle was found to contain 0·2 per cent total phosphorus, of which 0·16–0·17 per cent is inorganic phosphate. Assuming a moisture content of 81 per cent, this would correspond with a concentration of 0·97–1·13 gm. anhydrous disodium phosphate per 100 gm. water. In undried salt fish this figure should remain unchanged: only dry salt is added during salting, and the concentration of phosphate in the water held by the fish should be the same as in the pickle lost, unless some phosphate is held by the tissue. Such a solution, saturated with sodium chloride, would also be saturated with the disodium phosphate dodecahydrate at about 4° C.

After partial drying, the temperature of saturation with respect to the phosphate would be higher. In one sample of slightly dried heavy-salt fish, analysis for moisture and phosphate indicated that this temperature would be about 11° C. Drying therefore favours the formation of the crystals.

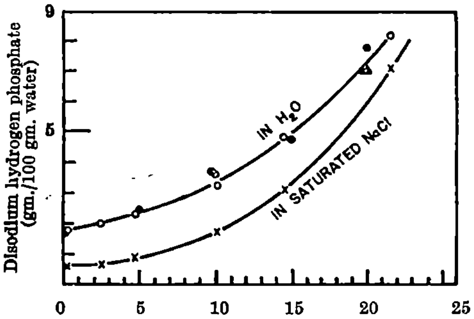

Fig. 1. Solubility of disodium hydrogen phosphate dodecahydrate in water and in saturated sodium chloride solution from 0° to 20° C. ●, In water, data from I.C.T. (ref. 1); ○, in water, experimental; ×, in saturated sodium chloride solution, experimental; △, in saturated sodium chloride solution (ref. 2)

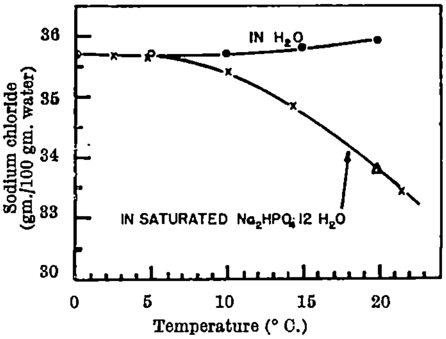

Fig. 2. Solubility of sodium chloride in water and in saturated disodium hydrogen phosphate dodecahydrate solution from 0° to 20° C. ●, In water, data from I.C.T. (ref. 1); ×, in saturated phosphate solution, experimental; △, in saturated phosphate solution (ref. 2)

A slightly alkaline *p*H (about 7·5–8) is also required for the formation of disodium hydrogen phosphate crystals. While the fish itself is almost neutral, most solar fishery salts are alkaline, and any slight spoilage (which often occurs with medium-salt fish) would also tend to increase the *p*H.

Thus the occurrence of these crystals on partially dried salt bulk fish, particularly while in cool storage or during transportation in the winter months, is readily explained. Its higher incidence with medium-cure fish probably depends on the susceptibility to rapid spoilage and the consequent elevation of the *p*H in this type of salt fish.

The effect of the sodium phosphate on the solubility of sodium chloride should also be noted. At 20° C. the solubility of the latter is only 93·9 per cent of the value in the absence of the phosphate. This explains why, in practice, salt fish is not often found in which the water is completely saturated with respect to sodium chloride when the solubility in salt-water systems only is considered, as is usually done.

Effect of Phenobarbitone on the Requirement of *Lactobacillus leichmannii* for Vitamin B_{12}

When sodium phenobarbitone (2 mgm. per ml.) is added to the medium used in a modified method for the microbiological assay of vitamin B_{12} with *Lactobacillus leichmannii* as test organism, an increase occurs in the amount of growth produced by small amounts of vitamin B_{12}[1]. This communication describes results which suggest that phenobarbitone has a specific vitamin B_{12}-sparing action under the experimental conditions previously described[1]. The strain of *Lactobacillus leichmannii* used was supplied by the National Collection of Industrial Bacteria, and is derived from the American Type Culture Collection strain No. 4797.

Table 1. THE EFFECT OF PHENOBARBITONE ON THE GROWTH OF *Lactobacillus leichmannii* IN THE PRESENCE OF VITAMIN B_{12}

		0·5	—	0·075	0·16	0·33	—	0·84	—

* Incubated in anaerobic jars under hydrogen.
† Using phenobarbitone recrystallized three times from water.

By comparing the amount of growth produced by different quantities of vitamin B_{12} in the presence and in the absence of phenobarbitone, the apparent increase in the concentration of vitamin B_{12} due to the presence of phenobarbitone could be assessed. The results, summarized in Table 1, show that phenobarbitone can cause nearly a sixfold increase in the apparent concentration of vitamin B_{12}. The effect is most marked at the lowest level of vitamin B_{12}, and it is as great after incubation for 72 hr. as after 24 hr. (exp. 3). Anaerobic incubation (exp. 4), and the use of recrystallized phenobarbitone (exp. 5) did not affect the results. Lower concentrations of phenobarbitone caused slightly less marked effects (exp. 6).

Higher concentrations of vitamin B_{12}, between 1 and 5 mμgm. in 5 ml. medium, produced almost the same amount of growth whether phenobarbitone was present or not. In several experiments the amount of growth at these levels of vitamin B_{12} was higher in the absence of phenobarbitone than in its presence.

To test the effect of phenobarbitone on growth in the presence of varying amounts of other growth factors, excess vitamin B_{12} (5 mμgm. in 5 ml. medium) was supplied, and either pteroyl glutamic acid or calcium pantothenate was omitted from the basal medium. With increasing amounts of pteroyl glutamic acid there was a slight reduction in growth in the presence of phenobarbitone over the whole range of concentration. With pantothenate there was a suggestion of stimulation of growth by phenobarbitone at the lower levels, but the effect was much less marked than with vitamin B_{12}.

If phenobarbitone was replaced by thymine or uracil at the same molar concentration, there was little change in the growth response to vitamin B_{12}. Some other barbituric acid derivatives have been tested, also at the same molar concentration as phenobarbitone. Barbituric acid itself had a depressant effect, diethyl barbituric acid had some stimulatory effect though less noticeably than phenobarbitone, while nembutal, amytal and butobarbitone appeared to have stimulatory effects similar to that caused by phenobarbitone.

The property of enhancing growth appears to be connected specifically with vitamin B_{12}, and to be confined to certain barbituric acid derivatives with relatively large substituents in the 5-position. No explanation of the phenomenon has been found, but in view of the chemical resemblance between the barbiturates and the iminazole part of the 5,6-dimethyl benziminazole in the molecule of vitamin B_{12}, it seems possible that barbiturate radicals might replace the benziminazole in vitamin B_{12}, forming analogues of vitamin B_{12} with greater growth-stimulating activities for *Lactobacillus leichmannii* than vitamin B_{12} itself. Experiments are in progress to test this possibility.

I wish to thank Prof. D. D. Woods, of the Microbiology Unit, Department of Biochemistry, University Museum, Oxford, for advice in connexion with these experiments. Thanks are also expressed to Prof. L. J. Witts for his interest in the work, and to Mrs. Elisabeth Ross for assistance with the microbiological assays.

Resistance to Dieldrin in *Lucilia cuprina* Wied., the Australian Sheep Blowfly

WHILE the modified Mules operation[1] greatly assists in reducing the incidence of fly strike of sheep in Australia, chemicals also have an important role in sheep blowfly prevention and control. In agreement with other sheep-raising countries, dieldrin and aldrin have been widely used here for the past three years for the prevention of attack by sheep blowflies.

These insecticides, when used at concentrations of 0·025–0·1 per cent, give periods of protection from 6 to 10 weeks and 12 to 16 weeks against breech and body strike respectively. Aldrin is frequently applied to sheep at twice the concentration of dieldrin.

While dieldrin and aldrin are still affording satisfactory protection against fly strike in sheep throughout New South Wales, there have been recent isolated instances of strikes occurring on sheep within 7–14 days of treatment with either of these insecticides. Field inquiries revealed that the chemicals had been correctly applied, and indicated that insecticidal resistance may have been acquired by *Lucilia cuprina*, which initiates fly strike in sheep in many areas in Australia.

Small numbers of adult flies recently hatched from larvæ, obtained from active strikes on sheep on three properties, currently experiencing difficulty in preventing fly strike with either aldrin or dieldrin.

Comparative toxicity tests have been conducted on flies from the three field strains and from a normal laboratory colony. In this work dieldrin was dissolved in kerosene containing 10 per cent acetone. A volume of 0·25 ml. of insecticidal liquid was applied to the thorax of female flies, seven to ten days old, by means of a microburette[2] while the insects were immobilized with carbon dioxide. The flies were treated with a range of concentrations of 0·01–1·0 per cent dieldrin. The flies were placed, following treatment, in glass containers standing on blotting paper and covered with Petri dish lids. Water and sugar were provided, and mortality records were taken 24 hr. after treatment.

The *LD*50 for the normal laboratory and one field strain of flies is approximately 0·025 μgm. of dieldrin per female fly. Two field strains of flies have an *LD*50 between 1·25 and 2·5 μgm. of dieldrin per female fly. The *LD*50 dosages for the two resistant field strains may be in excess of the maximum figure shown, for the work was undertaken during a heat wave and there was no provision for lowering the temperature in the chamber in which the treated flies were held. Dieldrin has been shown to have a positive temperature coefficient with *Lucilia cuprina* in earlier investigations.

In addition to conducting tests with adult flies, tests were also made with prepupæ of field and normal strains. Prepupæ were immersed for 5 min. in emulsions of dieldrin and placed in sand following drainage. A complete hatch of flies was obtained from prepupæ of the field strains after immersion in 0·5 per cent dieldrin, but no flies emerged from prepupæ from the normal strain following treatment with 0·05 per cent dieldrin. The prepupæ from the field strains are at least ten times more resistant to dieldrin than those from the normal strain.

The demonstration of resistance to dieldrin in the two field strains of *Lucilia cuprina* reported here is interesting, for a very small increase in resistance has been obtained in a laboratory programme aimed at selecting for resistance to this insecticide. Laboratory selections have been made for twelve generations.

The resistance to dieldrin in the field strains could, however, explain the unsatisfactory results being obtained on the two properties concerned. In view of the rapid development of resistance of dipterous insects to dieldrin[3], it is highly possible that dieldrin resistance in *Lucilia cuprina* will appear in other areas. The laboratory investigations have been confined to studies on dieldrin owing to the small numbers of flies available for the tests. The work will be extended to include toxicity studies with other insecticides used for sheep blowfly prevention.

Tryptophan Content of Wool

Previous results for the tryptophan content of wool have given results varying from 0·5 to 2·3 gm. per 100 gm. of wool[1-7]. In the majority of cases the tryptophan has been determined after alkaline hydrolysis of the wool. Spies and Chambers[8] have shown that the determination of tryptophan in casein, after alkaline hydrolysis, is unreliable unless special precautions, such as the use of an atmosphere of hydrogen, are taken. They found that there is reaction of tryptophan with serine, threonine and cystine during hydrolysis, and, since wool contains larger amounts of these amino-acids than casein, the results are likely to be less reliable than those for casein. They developed a method for the estimation of tryptophan in intact proteins by reaction with *p*-dimethylamino-benzaldehyde in 19 *N* sulphuric acid which avoided these side reactions.

We have used a modification of this method to determine the tryptophan content of wool and have obtained very consistent results. 30 mgm. wool, of known moisture content, is added to a solution of 100 mgm. *p*-dimethylaminobenzaldehyde in 18·1 *N* sulphuric acid and the mixture allowed to stand in the dark at room temperature with occasional shaking, until the wool dissolves. This takes about one week. The blue colour is then developed by the addition of 0·1 ml. 0·01 *M* sodium nitrite solution and estimated with a Spekker photoelectric absorptiometer using Chance *OR*2 filters.

Table 1. Tryptophan Content of Wool

Wool	Fibre diam. (μ)	gm. Tryptophan per 100 gm. dry wool
Durban merino	16·0	1·07
Port Elizabeth merino	19·8	1·01
64's B.A.	21·3	0·97
56's New Zealand	23·9	0·95
56's Monterides	30·2	0·94
44's New Zealand	34·3	0·93

The tryptophan contents of a number of wool samples determined by this method are given in Table 1.

These results show that there is a tendency for the finer quality wools to contain more tryptophan than those of lower quality. This does not appear to be due to destruction by the sulphuric acid of some of the tryptophan in the coarser wools, since we have obtained the same tryptophan content for a sample of wool using sulphuric acid varying in strength from 17·1 *N* to 23·0 *N* and also using hydrochloric acid in place of the sulphuric acid.

The tryptophan content of a number of other keratins has been determined by this method and the results are given in Table 2.

Table 2. Tryptophan Content of Various Keratins

Keratin	gm. Tryptophan per 100 gm. dry keratin	Previous values
Wool (root ends)	0·93–1·07	0·5 (ref. 1), 0·7 (ref. 2), 0·94 (ref. 3), 1·45 (ref. 4), 1·8 (ref. 5), 2·1 (ref. 6), 2·3 (ref. 7)
Mohair	0·74	—
Camel hair	0·84	0·8 (ref. 2)
Cow hair	0·82	1·4 (ref. 2)
Human hair	0·54	0·7 (ref. 2), 1·0 (ref. 9)
Cashmere	0·97	—
Cow horn	0·84	0·7 (ref. 2), 1·43 (ref. 4)
Finger nails	0·66	1·1 (ref. 2)
Pigeon quill	1·08	—

These results show that the tryptophan contents of the keratin samples examined lie between 0·5 and 1·1 per cent. This contrasts with the occurrence of only trace amounts of tryptophan in various collagens[10,11] and suggests that determination of the tryptophan content of tissue proteins may be a convenient method for classifying the proteins as collagens or keratins.

We hope to publish a fuller account of this work in due course.

We wish to thank the directors of Wolsey, Ltd., for permission to publish this communication.

Polymely in *Xenopus laevis*

IN several genera of the order Anura supernumerary limbs occur naturally[1]. They are usually extra hind limbs[2]. Polymely does not appear to have been reported in the genus *Xenopus*. The female toad (*Xenopus laevis*) described here came with a consignment of toads imported from South Africa in 1956. The toad measured 8·0 cm. from snout to vent and weighed 60 gm. and, except for a supernumerary right arm, was quite normal in appearance. The additional forearm was a mirror image of the normal right arm and was the same size as the two normal limbs. It measured 3·2 cm. from the axilla to the tip of the longest digit. The additional limb was attached immediately anterior to, and in the same plane as, the normal right arm. The point of attachment of the two limbs formed a prominent bony lump (Fig. 1). The extra limb was functionally normal and capable of independent movement. *Xenopus* is aglossate and pushes food into its mouth with both hands. In this specimen the back of the supernumerary hand assisted the normal left hand to carry food to the mouth, and the normal left hand alone was used for pushing food into the mouth. This toad had no difficulty in competing with normal *Xenopus* for food and was well nourished.

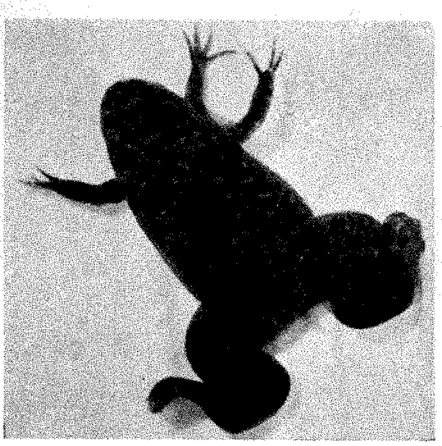

Fig. 1. Female *Xenopus laevis* with a supernumerary right arm

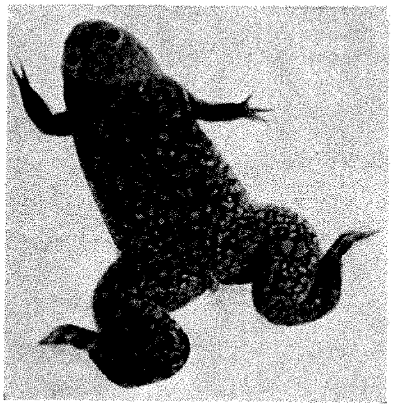

Fig. 2. The toad in the 'two-armed' position; supernumerary arm concealed

The toad had been in the laboratory for more than a year before its abnormality was noticed, and it was only discovered then because the toad was handled. Fig. 2 shows the animal in the 'two-armed' position; the supernumerary limb is concealed by the head. When the toad rested in this position it was indistinguishable from normal animals in the same tank. Accounts of supernumerary limbs in the Anura show that the extra limb is abnormal, being incomplete osteologically and deficient in muscle. This was not the case for the toad described here. The extra limb was functional, and had the same dimensions as the two normal fore limbs. This example of polymelia in the genus *Xenopus* appears to be the first that has been reported, and supernumerary limbs have never been described in the related genera *Pipa*, *Hymenochirus* and *Pseudohymenochirus*. During 1947–57, we have imported 23,250 toads from South Africa, and in the same period 6,480 *Xenopus* have been bred in this Laboratory. No other toad has had a supernumerary limb.

A New Type of Light Organ in the Deep-Sea Fish *Opisthoproctus*

IN the closely related salmonoid genera *Opisthoproctus* and *Monacoa* the ventral surface is formed as a flat sole reaching from under the head to the terminal or subterminal anus. Trewavas[1] found an organ immediately under the skin of the sole which she regarded as a swim-bladder. The question why these fishes, in contrast to all other known bathypelagic fish, should have a flat ventral surface and presumably swim upside down called for an explanation.

Dissections and serial sections of specimens from the *Dana* Oceanographical Collections revealed the following facts:

1. *Opisthoproctus* has a swim-bladder in the normal position (Fig. 1, *SW*).
2. The organ in the ventral sole (Fig. 1, *REFL*) is not a swim-bladder. Its lumen is completely filled with a very transparent gelatinous tissue and no *retia mirabilia* or gas gland is present.
3. As described by Trewavas, the so-called swim-bladder is posteriorly attached to a swelling of the rectum (Fig. 1, *RE*). The wall of this rectal bulb is strongly pigmented and contains numerous blood vessels. A sagittal section through the bulb shows that its posterior wall is covered inside by a thick luminous epithelium of similar appearance to that found in the light-organs of ceratioids. Like these, this light-organ is an open gland most probably containing luminous bacteria. In front of the

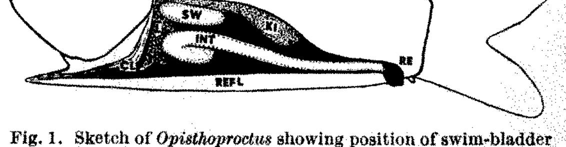

Fig. 1. Sketch of *Opisthoproctus* showing position of swim-bladder (*SW*), rectal light-organ (*RE*) and its reflector organ (*REFL*). Paired fins and gonad removed. (*CL*, cleithrum; *KI*, kidney; *L*, liver)

luminous epithelium is a transparent lens-like structure consisting of two lateral halves filling the rest of the bulb, leaving only a narrow slit for the passage of the fæces.

4. The wall of the rectal bulb, which elsewhere is thick and pigmented, has a very thin and completely transparent window where it is attached to the bladder-like organ of the ventral sole. Dorsally the inner surface of this 'bladder' has a silky brilliance.

Evidently the function of the organ in the sole of *Opisthoproctus* is to serve as a reflector for the rectal light-organ. The light is transmitted through the lens and window of the bulb to the crystal-clear tissue of the reflector organ. From the shining ventral wall of the latter the light is reflected downwards and dispersed over the whole ventral surface of the fish. The flat sole is covered with large thin scales which are transparent at the base but pigmented with increasing density towards the distal edge. A shortening of the sole will thus screen the light.

Probably the main biological significance of this complicated organ is that it enables the fish to be recognized by others of its kind which have sensitive, upwardly directed, tubular eyes. Possibly a very low light intensity is sufficient for this purpose. This would greatly reduce the risk of being detected by predators, and furthermore the downwardly directed light from the flat sole will be difficult to observe by fish with normal horizontally directed eyes.

Somewhat similar types of light-organs with open glands connected more or less directly with the intestine, and emitting light indirectly through transparent parts of the body, have been found in some Percomorphi from shallow water: *Acropomona japonicum, Leiognathus equula, Gazza minuta* and *Apogon marginatus*[2-5].

A more detailed report on the rectal light-organ of *Opisthoproctus* and related genera is under preparation and will appear in the "*Dana* Reports".

Effect on Earthworm and Diptera Populations of BHC Dust applied to Soil

IT is well known that BHC affects earthworms and soil insects. A review of these problems has been given by Satchell[1].

In May 1956, 12 per cent γ-BHC dust was applied at surface concentrations of 10·08, 20·16, 28·8 and 57·6 gm./100 m.² to ploughed plots and was thoroughly mixed with soil to a depth of 4 in. In 1956 and 1957 the plots were sown with sugar beet and potato. In October 1957 (18 months after treatment with BHC) the earthworms and other fauna were extracted from the experimental plots.

A significant increase in the earthworm population occurred in all the plots treated with BHC (Table 1). This may be partly explained by 'food mobilization' in soil treated with BHC[2].

A statistical examination has shown that there is a curvilinear correlation (parabolic) between BHC concentration and the number of earthworms. The optimal γ-BHC concentration is 31·03 gm./100 m.². This gives the highest number of earthworms.

Table 1. EFFECT OF BHC ON NUMBERS OF EARTHWORMS IN POTATO PLOTS

gm./100 m.² of γ-BHC	No. of earthworms per m.²
Untreated	10·0
10·08	21·6
20·16	25·8
28·8	26·1
57·6	14·6

Table 2. EFFECT OF BHC ON POPULATIONS OF WIREWORM AND DIPTERA IN SUGAR BEET PLOTS

gm./100 m.² of γ-BHC	No. per m.²	
	Wireworm	Diptera
Untreated	1·1	3·6
10·08	0·2	4·3
20·16	0·2	6·0
28·8	—	7·1
57·6	—	6·6

It was observed (Table 2) that on all treated sugar beet plots the number of wireworm was reduced and the population of Diptera (*Pegomyia hyoscyami* and others) was increased. It is suggested that the significant increase in the number of Diptera in all plots treated with BHC was due to a reduction in predators, the numbers of wireworm. Similar results were obtained by Stone[3] with the wireworms *Limonius californicus* and *Hylemyia ciliclura*.

Thermocline off the Coast of Tropical West Africa

RECENTLY, Salzen[1] has shown that there is a marked difference with depth in the species composition of the demersal fish fauna off Tema in Ghana. He found that there was a distinct change from euryhaline and eurythermal species in the shallow inshore water, to red and brown marine species below 10 fathoms. As the same change in species had been observed by Postel[2] working off French Guinea, Salzen suggested that the results for Tema might be typical of a great deal of the West African shelf in the dry season. The results (unpublished) of an extensive, though not detailed, hydrographic survey of the region, from Dakar to the Cameroons, made during 1952, tend to support such a generalization, and pose the question as to whether the thermocline might be partly responsible for determining the distribution of the inshore fish fauna.

During the course of the hydrographic survey, a number of bathythermograph recordings were made at stations distributed in transects at various intervals along the West African shelf. Salinity samples were also taken using a Nansen Peterssen insulated water-bottle. The results of the survey were in close agreement with the observations of Defant[3] made during the *Meteor* Expedition of 1925–27. It was found that the deeper water on the shelf was separated from the surface waters by a layer within which the density increased so rapidly with depth that it had the character of a discontinuity layer and within this layer there was a distinct salinity maximum. The discontinuity layer or thermocline covered the whole area of the survey and showed a slight slope to seawards.

The water masses above the thermocline showed a small and irregular vertical temperature gradient, but within the thermocline itself, the gradient was very marked—about 9 deg. C. in 13 fathoms off the coast of Sierra Leone, and about 4 deg. C. in 5 fathoms off Ghana. The salinity gradient was most pronounced in the surface waters, especially near the coast. On proceeding away from the coast, the salinity of the surface waters increased rapidly, and at the same time the temperature decreased. Off the coast of Ghana, however, this tendency was reversed, presumably as a result of upwelling near the coast. In this region, colder and more saline water was found close to the surface inshore, and as a result the thermocline had a smaller vertical extension than elsewhere in the area of the survey.

Table 1. AVERAGE DEPTH OF THE THERMOCLINE OFF THE COAST OF THE BRITISH WEST AFRICAN TERRITORIES

Coast	No. of stations	Average depth from surface	
		Bottom of surface water (fathoms)	Bottom of thermocline (fathoms)
Gambia	12	10	24
Sierra Leone	10	12	28
Ghana	14	10	15
Nigeria	16	15	26

The average depth of the thermocline is indicated in Table 1. It will be seen that the bottom of the surface water approximates to that depth (10 fathoms) at which Postel and Salzen observed the change from euryhaline and eurythermal species to predominately marine. This suggests that the thermocline probably plays some part in determining the nature and distribution of the inshore fish fauna of West Africa. Unfortunately, the results of the 1952 hydrographic survey are insufficient to allow any precise relationships to be determined, but in view of the fact that the thermocline is a constant and widespread feature of the waters on the West African shelf, its presence should, perhaps, be considered as a contributory cause of the correspondence between the Tema area and the French Guinea shelf.

Bixbyite from Nagpur

DURING an examination of polished sections from Prof. A. M. Bateman's collection of Indian manganese made during his trip in 1954 (1232*a*, Joda East Nagpur), I noticed a few grains of a greyish white mineral with a distinct yellow tint and a slightly greater hardness than braunite, with which it is associated. Etch tests with nitric acid, potassium cyanide, stannous chloride and hydrogen peroxide were negative. Microchemical tests indicated the presence of manganese and iron. X-ray photographs of the mineral were taken by the Debye–Scherrer method using iron *K* radiation. The *d* spacings observed from the film, as given in Table 1, agree fairly well with the values obtained by Fleischer and Richmond[1] for bixbyite from the Thomas Range in Utah.

Table 1

d	*I*	*d*	*I*	*d*	*I*	*d*	*I*
4·52	1	2·14	6	1·49	1	1·10	2
3·34	1	1·87	1	1·46	2	1·14	1
3·19	2	1·80	2	1·40	8	1·07	8
2·98	1	1·71	1	1·35	2	1·05	7
2·73	10	1·66	9	1·25	1	1·03	2
2·33	4	1·53	2	1·17	1		

d, Spacings in Angstrom units; *I*, estimated intensities

Fleischer and Richmond give the formula $(Mn/Fe)_2O_3$ for bixbyite. Mason[2] has shown the chemical similarity and structural identity of bixbyite and sitaparite.

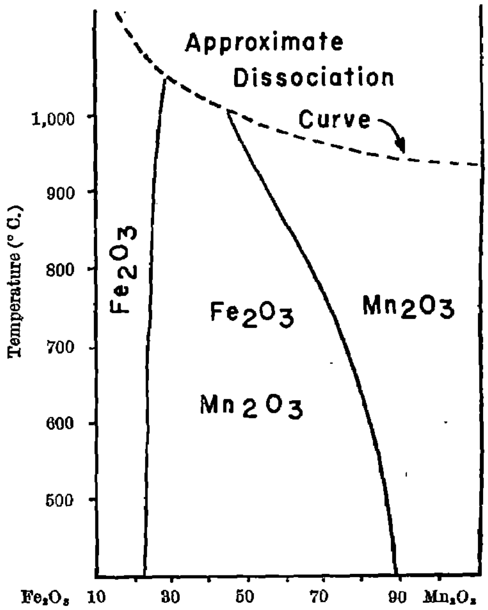

Fig. 1. The system Fe_2O_3—Mn_2O_3 (after Mason, *Amer. Mineral.*, 29; 1944)

Fig. 1 indicates that the solubility of Fe_2O_3 in Mn_2O_3 increases with increasing temperature.

Bixbyite formed at high temperatures contains 45–60 per cent Fe_2O_3. Sitaparite formed during metamorphism of manganese ores contains about 30 per cent Fe_2O_3. Unmixing of these minerals into iron-poor sitaparite and iron-rich bixbyite has significance in geological thermometry.

Bixbyite has been reported from many localities including Patagonia, Sweden, South Africa, Utah and New Mexico. A survey of the literature shows that this is the first report of the mineral from India.

The above observations were made during a study of Indian manganese ores at the Laboratory of Economic Geology, Yale University.

I am grateful to Prof. Alan M. Bateman for his direction and valuable help.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, March 24

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. W. G. V. Balchin: "A Water Use Survey".

Monday, March 24—Thursday, March 27

Physical Society (in the Old and New Halls of the Royal Horticultural Society, off Victoria Street, London, S.W.1)—Annual Exhibition of Scientific Instruments and Apparatus.

Tuesday, March 25

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. Gerald Lacey: "Flow in Alluvial Channels with Sandy Mobile Beds".

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. L. Essen: "The Atomic Clock".

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. D. K. Hale: "Ion Exchange Resins".

Royal Photographic Society (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Annual General Meeting.

Tuesday, March 25—Thursday, March 27

Institution of Naval Architects (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1), at 10.15 a.m. daily—Spring Meeting.

Society of Chemical Industry (at the University, Aberdeen)—Conference on "Fundamental Aspects of the Dehydration of Foodstuffs".

Wednesday, March 26

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. N. L. Falcon and Dr. P. E. Kent: "The Geological Results of Petroleum Exploration in Britain, 1945 to 1957".

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Dr. V. R. Gray: "The Dewatering of Fine Coal".*

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. F. Giordani: "The Objective for Euratom".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. W. J. Perkins and Dr. M. H. Evans: "Electronics in Medical Research".

Society for Analytical Chemistry, Biological Methods Group, (in the Physiology Laboratory, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Demonstration Meeting.

Royal Institute of Chemistry (joint meeting with the Chelsea College of Science and Technology Chemical Society, at the Chelsea College of Science and Technology, Manresa Road, London, S.W.3), at 7 p.m.—Dr. F. L. Rose, F.R.S.: "Chemotherapy".

Thursday, March 27

Photobiology Group (at Bedford College, Regent's Park, London, N.W.1), at 2 p.m.—Dr. C. A. Parker: "Recent Advances in Spectrofluorimetry and Chemical Actinometry"; Dr. R. S. Spencer: "The Biology of Luminous Bacteria"; Mr. E. S. Trickett: "Problems of Radiation Measurement in Relation to Environmental Control".

Bone and Tooth Society (in the New Lecture Theatre, The Hospital for Sick Children, Great Ormond Street, London, W.C.1), at 5 p.m.—Symposium on "Eosinophilic Granuloma and Related Conditions". Speakers: Dr. Reginald Lightwood, Dr. John Sutcliffe and Dr. Martin Bodian.

Oil and Colour Chemists' Association (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. C. C. Mill: "Some Observations on the Rheology of Carbon Black Suspensions".

Thursday, March 27—Friday, March 28

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2)—Convention on "Radio Aids to Aeronautical and Marine Navigation".

Friday, March 28

Biochemical Society (at the University of Birmingham Medical School), at 11 a.m.—Scientific Papers.

British Psychological Society, Industrial Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mr. J. N. Bamforth: "Human Relations Training at Roffey Park—an Experiment in Evaluation of Results".

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on papers received during the Session 1957–58. Chairman: Dr. R. Stoneley, F.R.S. Speakers: Dr. A. H. Cook, Mr. H. M. Iyer, Sir Harold Jeffreys, F.R.S., and Mr. A. S. Merriweather.

Medical Research Council (at the National Institute for Medical Research, Mill Hill, London, N.W.7), at 5 p.m.—Prof. N. I. Kalabukhov (Institute for Scientific Research, Ministry of Health, Saratov, U.S.S.R.): "Seasonal Changes in the Organism of Mammals in Relation to the Environment".

Institution of Mechanical Engineers, Internal Combustion Engine Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Ultimate Engine: Stationery, Rail Traction and Marine".

Royal Photographic Society, Kinematograph Group (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Annual General Meeting, followed by a review of recent apparatus, by Mr. A. R. Rigg.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. Richard Julius Pumphrey, F.R.S.: "Hearing in Man and Animals".

Friday, March 28—Saturday, March 29

Linnean Society of London (in the Lecture Theatre of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.45 a.m. Friday and 10.15 a.m. Saturday—Symposium on "The Uses of the Electron Microscope in Biology".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant (Scientific) in the Department of Physiology and Plant Culture, for routine duties connected with plant studies in controlled environments—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford, Herts (March 27).

Scientific Officer (with an honours degree in plant physiology) in the Irrigation Section—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (March 28).

Assistant Physicist, Basic grade (with an honours degree in physics), for duties mainly in the X-Ray Diagnostic Department—The Personnel Officer, St. Thomas's Hospital, London, S.E.1 (March 29).

Hospital Biochemist, Senior grade (with a university degree in science or equivalent qualification), in the routine Biochemical Section of the Department of Clinical Biochemistry—The Administrator, Radcliffe Infirmary, Oxford (March 29).

Demonstrator in Physics—The Registrar, The University, Hull (March 31).

Nuffield Science Teaching Fellow (with a good honours degree in physics and preferably some experience in research or advanced study) in the Physics Department of the Faculty of Science, to pursue research in physics and at the same time participate in teaching at local grammar schools—Prof. Samuel Devons, Physical Laboratories, The University, Manchester 13 (March 31).

Junior (Assistant) Lecturer in Biochemistry, with special reference to physical biochemistry—The Dean, Guy's Hospital Medical School, London, S.E.1 (April 1).

Lecturer (honours graduate) in Physics at Kumasi College of Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (April 4).

Imperial Chemical Industries Research Fellows in Chemistry, Physics, Engineering (including Chemical Engineering), Metallurgy, Pharmacology or related subjects—The Registrar, The University, Sheffield (April 5).

Reader in Soil Science—The Secretary, The University, Aberdeen (April 7).

Lecturer (preferably with experience in reactor physics or nuclear metallurgy) in the Nuclear Engineering Laboratory—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 8).

Senior Tutor (Physicist) (preferably with university teaching experience) in the Department of Physics—The Registrar, University College of Swansea, Singleton Park, Swansea (April 8).

Lecturer in Civil or Mechanical Engineering—The Registrar, University College, Singleton Park, Swansea (April 10).

Research Fellow (with a Ph.D. degree or equivalent experience) in the Chemistry Department, for work on the kinetics of gaseous oxidation—The Professor of Chemistry, The University, Hull (April 10).

Assistant Lecturer in Geography, and an Assistant Lecturer in Philosophy—The Registrar, The University, Leicester (April 12).

Turner and Newell Research Fellow in Engineering, Inorganic Chemistry or Physics or other allied science—The Registrar, The University, Leeds 2 (April 12).

Lecturer (with special qualifications in physical chemistry) in the Department of Chemistry—The Registrar, University College, Singleton Park, Swansea (April 14).

Scientific Officer (with qualifications which include an honours degree in natural sciences), for research on resistance of sugar beet to beet eelworm—The Secretary, The School of Agriculture, The University, Downing Street, Cambridge (April 15).

Senior Lecturer (with a knowledge of tropical pastures and of animal nutrition in humid tropics) in Agriculture (Nutrition) at University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 20).

Lecturer (preferably with experience in electronics and instrumentation for automatic control) in Electrical Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 30).

Lecturer or Assistant Lecturer in Anatomy, and a Lecturer or Assistant Lecturer in Bacteriology at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 30).

Reader in Biochemistry at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 30).

Senior Leverhulme Research Fellow, for research in some aspects of radio-astronomy, using the radio-telescope at the Jodrell Bank Experimental Station—The Registrar, The University, Manchester 13 (April 30).

Lecturer or Assistant Lecturer (with interests in physical and/or inorganic chemistry) in Chemistry at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 3).

Leverhulme Students (graduates in chemistry or engineering) in Chemical Engineering, for advanced training or research in chemical engineering in the Ramsay Memorial Laboratory—The Registrar, University College, Gower Street, London, W.C.1 (May 15).

Lecturer in Physics at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 20).

Applied Mathematician, to provide mathematical services in forestry, fisheries and wild-life management research; a Forest Fire Physicist (preferably with a background in meteorology), to initiate a field research programme on physical and meteorological factors influencing growth and spread of forest fires; and an Oceanographer (physicist, preferably, with a background of hydrodynamics, meteorology or oceanography, and competent in mathematics), to lead scientific parties aboard the research vessel, taking oceanographic and meteorological observations, developing new observational techniques and instruments, analysing data and undertaking model work—Head of Physics Section, Division of Research, Department of Lands and Forests, R.R. No. 2, Maple, Ontario, Canada.

Assistant Professor in the Department of Physics—The University of New Brunswick, Fredericton, New Brunswick, Canada.

Assistant (with Inter.B.Sc. or equivalent qualifications including mathematics) in the Computing Machine Laboratory, for miscellaneous duties in connexion with the preparation of work for an electronic digital computer—Dr. T. Kilburn, The Department of Electrical Engineering, The University, Oxford Road, Manchester 13.

Head (mechanical engineer, with good teaching, industrial and/or research experience) of the Department of Engineering—The Principal, Welsh College of Advanced Technology, Cathay's Park, Cardiff.

Lecturer in Mathematics, to teach pure and applied mathematics to degree standard—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

Lecturer (with a suitable degree and industrial or research experience) in Metallurgy—The Deputy Registrar, The University, Birmingham 15.

Mass Spectroscopist (with a first- or second-class honours degree. and preferably research experience in mass spectroscopy and a knowledge of electronics and vacuum technology), to work on the development of a high-resolution mass spectrometer—Group Recruitment Officer (1045Y/34), Atomic Energy Research Establishment, Harwell, Berks.

Physicist, Experimental Officer or Assistant Experimental Officer grade (with at least G.C.E. in five subjects, with physics and one other scientific or mathematical subject at advanced level or equivalent), to work in a team engaged on specialized nuclear radiation measurements—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. 1733/34.

Technician (preferably with a knowledge of photography and/or geological techniques) in the Geology Department—The Registrar (GT), Queen Mary College (University of London), Mile End Road, London, E.1.

LECTURES AND COURSES

UNIVERSITY OF BIRMINGHAM

DEPARTMENT OF ENGINEERING PRODUCTION

M.SC. COURSE IN OPERATIONAL RESEARCH

M.SC. COURSE IN ENGINEERING PRODUCTION

DIPLOMA COURSE IN THE PRINCIPLES OF ENGINEERING PRODUCTION AND MANAGEMENT

Applications are invited for admission to the above one-year postgraduate courses in the session commencing in October, 1958. Admission as higher degree candidates is restricted to university graduates or non-graduates holding qualifications equivalent to a degree. Other suitably qualified applicants may be admitted to the Diploma course. Satisfactory industrial experience is required in all cases.

Details of these courses and other information may be obtained from the Registrar, the University, Birmingham, 15.

CHELSEA COLLEGE OF SCIENCE AND TECHNOLOGY

DEPARTMENT OF PHYSICS

SESSION 1958-59

" SANDWICH " COURSE IN PHYSICS

The next course, suitable for students engaged in industry, will begin on September 22, 1958. Students attend for two terms full-time and one term part-time in each session.

FULL-TIME COURSE IN PHYSICS

The next course will begin on September 22, 1958. Students must have the appropriate preliminary qualifications for registration as internal students for the B.Sc. Special Physics degree of the University of London.

Particulars and application forms may be obtained from the Secretary, Physics Department, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

CHELSEA COLLEGE OF SCIENCE AND TECHNOLOGY

MANRESA ROAD, S.W.3

DEPARTMENT OF GEOLOGY

Head of Department: W. E. Smith, M.Sc., F.G.S.

An advanced evening course of six lectures on " Hydrogeology and Water Supply " will be given by Dr. J. Ineson on Friday evenings, 7 to 8.30 p.m., commencing May 2, 1958. The course is intended for geologists working on water supply problems and engineers with a basic knowledge of geology.

Further particulars can be obtained from the Head of the Department of Geology.

OFFICIAL APPOINTMENTS

UNIVERSITY COLLEGE OF NORTH STAFFORDSHIRE

Applications are invited for Imperial Chemical Industries Fellowships tenable at the University College of North Staffordshire. Fellowships may be awarded for the purpose of carrying out original research in chemistry or physics for a period not exceeding three years. Applicants should preferably hold the degree of Ph.D. or have equivalent research experience. Annual stipend will depend upon age, qualifications and experience, but will be within the range £700 to £1,000 together with F.S.S.U. benefits.

Applications (two copies), stating age, details of education, career, and qualifications, publications, and an outline of the proposed research, together with the names of two referees, should be sent not later than March 31, 1958, to the Registrar, University College of North Staffordshire, Keele, Staffs, from whom further inquiries may be made.

CHESTER BEATTY RESEARCH INSTITUTE

INSTITUTE OF CANCER RESEARCH

ROYAL CANCER HOSPITAL

Graduate required for work involving applications of ultra-violet and interference microscopy, etc., in biology. Person with some postgraduate experience in microscopy and/or biology preferred. The post is permanent and superannuable, and salary will be on a scale in accordance with age and qualifications.

Applications, giving names of two referees and marked " EMFR," should be sent to the Secretary, Chester Beatty Research Institute, Fulham Road, London, S.W.3, by April 19, 1958.

AUSTRALIAN NATIONAL UNIVERSITY

RESEARCH SCHOOL OF PHYSICAL SCIENCES

Applications are invited for a Research Fellowship in the Department of Nuclear Physics. This Department, under Professor E. W. Titterton, has three accelerating machines in operation—600 KeV. and 1.25 MeV. Cockcroft-Walton accelerators and a 33 MeV electron synchrotron. The main programmes of work involve light element and photodisintegration studies. The salary will be within the range £A.1,350 to £A.2,000. The appointment will be for three years, with a probable extension to the maximum of five years. For an overseas appointee the appointment could be taken up at any convenient time during the year 1958. Superannuation on the Federated Superannuation System for Universities pattern will be provided and reasonable travel expenses will be paid.

Further particulars and information as to the method of application are obtainable from the Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1. The closing date for the receipt of applications, in Australia and London, is April 30, 1958.

UNIVERSITY COLLEGE OF SWANSEA

Applications are invited from Physicists with suitable experience, for a Senior Tutorship in the Department of Physics. University teaching experience is desirable. Salary on the Lecturer scale, £900 to £1,650 per annum. Commencing salary will be at a point on the scale determined by qualifications and experience. Membership of F.S.S.U. and children's allowance scheme.

Further particulars may be obtained from the Registrar, University College of Swansea, Singleton Park, Swansea, to whom applications (six copies), must be sent by April 8, 1958.

QUEEN MARY COLLEGE

(UNIVERSITY OF LONDON)

MILE END ROAD, E.1

Applications are invited for the post of LECTURER in the NUCLEAR ENGINEERING LABORATORY. The laboratory is primarily engaged in postgraduate teaching and research. Preference to candidates experienced in reactor physics or nuclear metallurgy. Salary scale £900 by £50 to £1,350 (efficiency bar): £1,425 by £75 to £1,650 plus London allowance £60 (initial salary according to qualifications and experience) with F.S.S.U. participation and family allowance of £50 for each child.

Details and application form (returnable by April 8) obtainable from the Registrar.

UNIVERSITY OF LEEDS

DEPARTMENT OF PATHOLOGY

Applications are invited from graduates in medicine or science (if the latter, preferably with a Ph.D. in one of the medical sciences) for appointment to the Lyons Fellowship for Multiple Sclerosis and Allied Nervous Diseases of the annual value of £1,250 rising by £100 a year; the appointment will be for one year in the first instance, renewable for two further years.. Under the direction of the Professor of Pathology the Fellow will take part in a combined programme of research on the biology of myelin and the experimental pathology of the demyelinating diseases.

Applications (three copies), stating date of birth, qualifications and experience, together with the names of three referees, should reach the Registrar, The University, Leeds, 2 (from whom further particulars may be obtained), not later than April 14, 1958.

UNIVERSITY COLLEGE OF SWANSEA

Applications are invited for a Lectureship in the Department of Chemistry. Candidates must have special qualifications in physical chemistry Salary on the scale £900 by £50 to £1,350 by £75 to £1,650 per annum. Commencing salary will be at a point on the scale according to qualifications and experience. Membership of F.S.S.U and children's allowance scheme.

Further particulars may be obtained from the Registrar, University College, Singleton Park Swansea, to whom applications (six copies) must be sent by Monday, April 14, 1958.

UNIVERSITY OF LIVERPOOL

NUCLEAR PHYSICS RESEARCH LABORATORY

Applications are invited for the following vac cies: (a) Physicist or Engineer to co-operate the design and development of a large liq hydrogen bubble chamber and associated pla for use in high energy nuclear physics resear Salary according to qualifications and experienc (b) Draughtsman to work with above. Sal range £700 to £900 per annum.

Applications, in writing, quoting Reference N 220(a) or 220(b), stating experience and qualific tions, together with the names of two refere should be sent to the Registrar, the Universi Liverpool, 3.

COMMONWEALTH BUREAU O SOILS

ROTHAMSTED EXPERIMENTAL STATIO

HARPENDEN, HERTS

Scientific Assistant required for work in scient information service involving abstracting and dexing. Good science degree, reading knowle of two European languages (preferably other th French or German) and ability to write go English essential. Knowledge of soil science a plant physiology an advantage. Salary scale £5 to £970 (bar) to £1,330 (bar) to £1,460. Ag qualifications and experience considered wh fixing starting salary. Up to two increments f compulsory National Service and two extra inc ments after two years' satisfactory service. Pr vision for superannuation.

Apply at once to Director, stating age, quali cations and experience.

UNIVERSITY OF WESTERN ONTARIO

DEPARTMENT OF PHYSICS

RESEARCH ASSOCIATESHIPS IN EXPERIMENTAL AND THEORETICAL PHYSICS

Applications are invited for postdoctoral a predoctoral Research Associateships in experime tal and theoretical chemical physics tenable The Molecular Excitation Group from Augus 1958. The research interests of the group cov a wide range of excitation problems related combustion, radiation chemistry, astrophysics, an atmospheric physics.

Further information may be obtained by writi by air mail to Dr. R. W. Nicholls, Departme of Physics, University of Western Ontari London, Ontario, Canada.

UNIVERSITY OF MANCHESTER

There is a vacancy in the Computing Machin Laboratory for an Assistant for miscellaneo duties in connection with the preparation of wo for an electronic digital computer. Inter.B.Sc. c equivalent qualifications including mathemati required. Facilities available to attend approve courses of higher education. Salary in accordanc with the University's scales.

Applications should be sent to Dr. T. Kilburn The Department of Electrical Engineering, Oxfo Road, Manchester, 13.

UNIVERSITY OF MANCHESTER

I.C.I. FELLOWSHIPS

Applications are invited for the above Researc Fellowships, founded by Imperial Chemical In dustries, Ltd., tenable in the University and avail able for research in Chemistry, Physics and allie subjects, e.g., Pharmacology, Engineering, Meta lurgy. The value of the Fellowships will be with in the range of £700 to £1,000 per annum accor ing to qualifications and experience.

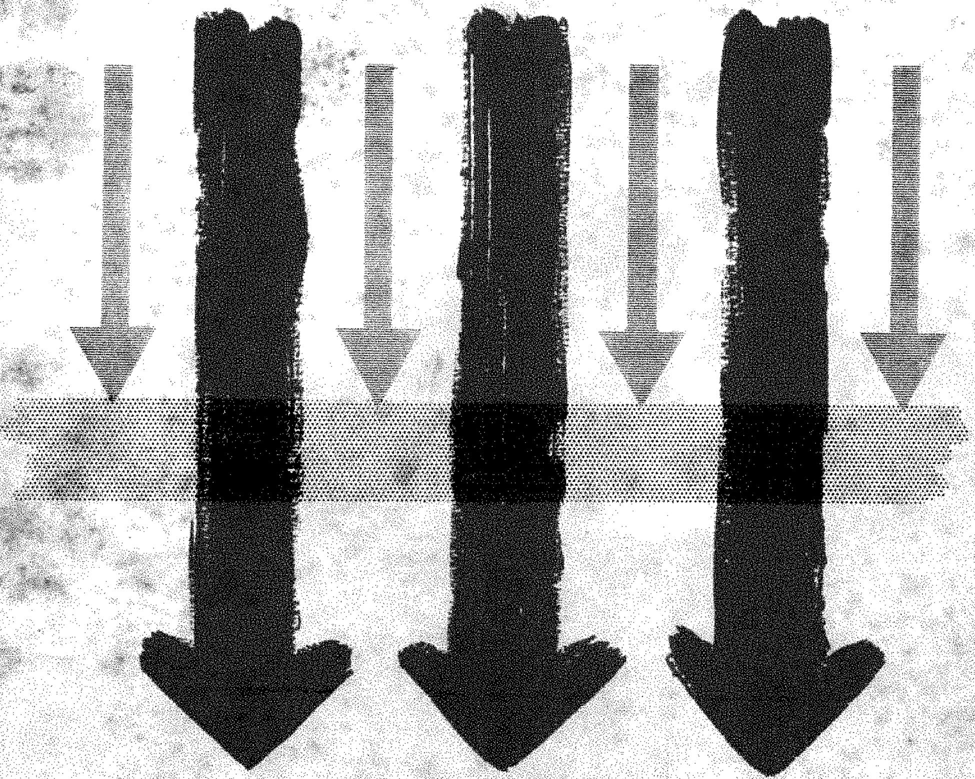
Regulations governing the award of the Fellowships may be obtained from the Registrar, The University, Manchester, 13, to whom application should be sent not later than April 30, 1958.

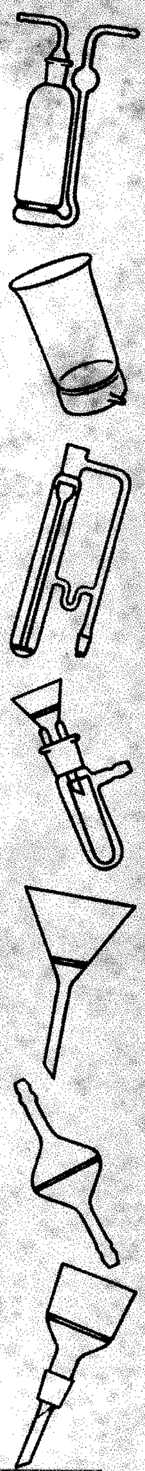
UNIVERSITY OF MANCHESTER

Applications are invited from suitably qualified graduates for posts in the Department of Electrical Engineering as Lecturer or Assistant Lecturer Candidates should have some experience in any of the branches of electrical engineering. The salary scales are as follows: Lecturer, £900 to £1,650 per annum, Assistant Lecturer, £700 to £850 per annum: initial salary and status according to qualifications and experience. Membership of F.S.S.U. and children's allowance scheme.

Applications should be sent not later than March 31, 1958, to the Registrar, The University, Manchester, 13, from whom further particulars and forms of application may be obtained. Overseas applicants should send letters of application (no forms), as soon as possible, giving details of qualifications and experience, and should submit the names of at least three persons to whom reference may be made.

B.T.L. Sintered Glassware





for filtration

B.T.L. Sintered Glassware is resistant to all reagents except hydrofluoric acid and strong alkalis. Grades from pore sizes 00 to 4 give a complete range from rough filtration of coarse precipitates to the "bright" filtration of the finest precipitates uch as barium sulphate. Grade 5 filters, specially made and conforming to B.S. 1752-1952, are increasingly replacing ceramic filters for bacteriological work. B.T.L. Sintered glass filters are being used by Glaxo Laboratories Ltd. in the manufacture of poliomyelitis vaccine and influenza virus vaccine.

A full list of the range will be sent on request.

CONNECTIONS

"Speedivac" demountable vacuum pipe connections require just a few turns of the wrist and you achieve a permanently rigid leak-proof pipe connection. No special tools are needed and they are designed for the *lowest* pressure systems. All sizes.

VALVING

'SPEEDIVALVES"—high vacuum diaphragm valves which provide *absolute* vacuum tightness when closed. There is complet freedom from spindle leakage and they incorporate a specia wear-resisting diaphragm.

GAS CONTROL NEEDLE VALVES—precision instrument-finished valves for the fine control of gas flows.

MAGNETICALLY OPERATED VALVES—designed for the *automatic* control of operational and protection devic range available.

ROTARY VACUUM

They facilitate the design of rotary movem systems. Positive vacuum sealing.

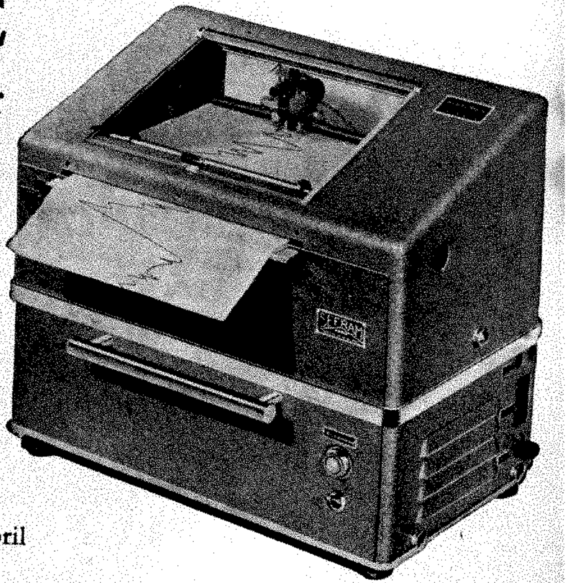
TAS/DO.1

A new valuable tool for research . . .

the **PHOTODYNE**

Spot Follower Pen Recorder

for use with any mirror instrument as galvanometers, electrometers, magnetometers, balances, viscosimeters, micromanometers, dilatometers, etc.



- Replaces photographic recording
- Works in a normally lighted room
- Records with 0·1% accuracy
- Writing speed up to 600 mm/sec.
- Potentiometer read-out for regulating or mathematical analysis if desired

See it at the IEA Exhibition, Olympia, London, 16-25 April

SEFRAM PARIS **74 rue de la Fédération, PARIS**

Also makers of RAPIDGRAPH high-speed pen recorders, sole European representatives for SCHLUMBERGER - PICARD antivibration and shock-proof galvanometers.

THE COUNCIL FOR NATURE

THIS year, which sees the celebration of the centenary of the Darwin–Wallace joint statement on natural selection, will also witness, more quietly, several consequences of that statement. Darwin's emphasis upon observation in the field and the importance of searching the rocks for fossils, gave a new stimulus to natural history, and it must be more than mere coincidence that the decade following that statement and, afterwards, the publication of the "Origin of Species"—saw the formation in Britain of an impressive number of naturalists' societies, mechanics' institutes and museums. Clearly, there was then a determination among ordinary people to examine for themselves the facts of Nature.

The pendulum of public interest has swung many times since then, and may currently be said to incline more favourably towards archæology. None the less, many of the societies and field clubs so founded linger on, though in but few is there much evidence of the enthusiasm in which they were so bravely launched. Records testify to the passing away of several proud names and the cessation of journals that were once useful and of wide circulation.

These facts are of importance, for it is clear that there is still need of their former activity. The statement that "all data in natural history are vanishing data" has seldom been so obviously true. The need to collect, collate and to conserve the materials of Nature is urgent. Even such tasks as the observation of the pollution of streams and the deterioration of roadside verges, well within the competence of local societies, are being neglected. Unfortunately, even among continuing bodies, activities seem to be desultory. Useful surveys are begun but fail to be maintained. It is true that there are some few notable exceptions in this depressing picture, and that there are 'unions' of scientific societies, regional affiliations which in some instances, as in the South Eastern Union, have organized programmes and an annual conference.

Naturalists are not alone in facing these problems. After the Second World War, the archæologists took stock of their affairs and, after consultation with local societies, university extra-mural departments and other interested organizations, on a broad and democratic basis, formed the Council for British Archæology, now so ably led by Prof. W. F. Grimes. These and other considerations have suggested to the Society for the Promotion of Nature Reserves that something could be done equally for the propagation and revival of interest in Nature, for the formation of local nature reserves, and the encouragement and co-ordination of appropriate societies.

As a result of these deliberations, a small working party was formed, including representatives of the Society for the Preservation of Nature Reserves, the Council for Field Studies, the Nature Conservancy, several societies and naturalists' trusts, and plans were made for the formation of a Council for Nature. These plans were made public and were freely discussed at a special meeting held in the rooms of the Linnean Society on February 19, and as a result a Council for Nature and a provisional committee were set up under the presidency of Lord Hurcomb and the chairmanship of Sir Landsborough Thomson. The immediate task of the committee is to consult the wishes and investigate the needs of local societies and regional organizations.

This inauguration, which was thought by some to be rather premature, is in fact most opportune. The Carnegie United Kingdom Trust has recently evinced an interest in the amateur in field studies of archæology and natural history, and has discovered the difficulty of finding a representative body with which to discuss aims and methods. As a direct consequence, the British Association has accepted a grant from the Trust to undertake the preparation of a directory of cognate scientific societies. This work is in active progress, its committee endeavouring to steer a course between the eight hundred or so societies that are strictly relevant and the two thousand or more that have a tenuous connexion, usually a sporting interest, with some aspect of botany and zoology. There is no doubt that this directory will provide a valuable basis for consulting all the societies claiming activity in some field of Nature.

But societies, even giving them their full due, are not the only interested parties. There are national bodies, some of which have expressed a desire to co-operate fully with the new Council, that are concerned with much wider aims. The advance of science is frequently a mixed blessing: the claims of technology being made, and sometimes carried, at the expense of natural amenities. Reasonable compromise is often possible and occasionally takes place, but who can really speak for the whole body of naturalists ? With no active voice at the moment, representations made on reasonable grounds are sometimes feeble, often conflicting and frequently ill-argued. The Nature Conservancy, powerful and experienced and friendly to local interests, is none the less a government department, and is hampered in its dealings with other government departments.

The Council for Nature has thus a primary function to fulfil: that of watchdog—but not necessarily that of unflinching opponent—of all schemes alleged to spoil the countryside. It is important to stress that the Council will not exist as a purely restrictive body. The national parks of Britain, with all their problems caused by the access of some members of the public to places of beauty, may welcome its aid. Public education and information may be found, in the long run, more rewarding than compulsion or interference with public freedom. The Council of Nature is, by its origin, favourable to the interests of the amateur, the hiker, the photographer and the bird watcher—the general public of the parks. As yet, in Britain, we lack the service of guides and instructors, so commendably provided by the National Parks Organization of the United States. We would commend the American service to the new Council, and suggest that co-operation and some early exchange of staff would be rewarding.

Education in Nature need not, however, begin either on the hillside or by the seashore. There is need for instruction in schools from members, say, of a special panel of lecturers. Courses for adults could be arranged in evenings in museums and colleges, clubs and societies. More general education by books, pamphlets, guide leaflets (as in the United States), by television and radio could do—and already is doing—much to make an intelligent and constructive approach to the study of Nature and to denigrate careless and destructive actions.

Much of this day-to-day work cannot, of course, be done best by a central body, and much will depend and devolve upon local groups, trusts and societies; but it must be rationalized and co-ordinated. Consideration of surveys that should be undertaken by societies can be made, programmes devised, inaugurated and some continuity of effort guaranteed. This should make for efficiency and economy in general work on natural history.

The foundation of local naturalists' trusts, on the lines of those in Lincolnshire, will obviously be one of the objects deserving the Council's support. Attention must also be paid to the lessening skills in certain aspects of amateur zoological and botanical work that seem to threaten accomplishment. Here instruction, encouragement and, perhaps, even subsidy can be given.

It is obvious that a wide field of liaison with societies, trusts and local interests on one hand, and with the Nature Conservancy on the other, can be effected, and this the Conservancy would no doubt welcome. Legal services too, where necessary, can be organized. Close co-operation with the British Association, the Council for the Preservation of Rural England, the similar council for Wales, the Council for Field Studies, and university departments can be assured from their representatives on the provisional committee. Conservation is still in its youth in Britain. Much needs to be done to make its aims more clear to the general public and to remove that feeling of interference that the name seems to convey in some quarters.

None of this work, least of all a journal devoted to its interests, can be done without adequate finance. The Society for the Promotion of Nature Reserves has generously promised to bear much of the expense of the inaugural years. When the aims of the Council become more legally defined in its constitution and more clearly appreciated, it may be that one of the benevolent financial trusts may see in the new body the organization that naturalists and nature-lovers have long desired. What must be clearly emphasized is that the Council for Nature proposes to act as co-ordinator and agent, as protector, and not suppressor, of local interests. There is room in it for all who love Nature and who respond to Emerson's lines:

> "Hast thou named all the birds without a gun ?
> Loved the wood-rose, and left it on its stalk ?"

The title of that poem might well be the motto of the Council for Nature itself—Forbearance.

PRACTICE FORESHADOWING SCIENCE

Robert Bakewell

Pioneer Livestock Breeder. By Prof. H. Cecil Pawson. Pp. xv + 200 + 10 plates. (London: Crosby Lockwood and Son, Ltd., 1957.) 25*s.* net.

VERY often old farming books propound theories or describe practices that seem to indicate that their writers had some inkling of the principles of modern science. It is extraordinarily easy to accept this conclusion, because it is very difficult to re-create in one's mind the condition of knowledge at a given date. When a great innovator like Robert Bakewell has written nothing about his theories, and left no record of his practice, this difficulty becomes almost insuperable.

Bakewell left the record of his success in the animals he produced—horses, cattle, sheep and pigs; but he was secretive about his methods. When Prof. H. C. Pawson discovered the letters published here for the first time, there was some hope that more would be revealed about the way in which Bakewell bred such fine animals, that made him so famous, both in his own day and in the esteem of posterity. In this respect the letters are disappointing, but they have provided a good reason for an attempt to write a monograph on this important man, about whom only a few brief periodical appreciations have been written in the past. The character of the man and some of his business methods are more closely delineated in these new letters.

The additional resources provided by the fodder crops, introduced from the Low Countries in the seventeenth century, and developed in English farming in the eighteenth century, had provided a means of feeding better cattle. Before that time there were so-called breeds, but these animals were all subjected to restricted nutrition in the winter, as indeed their owners were. The consequence was that, while almost every county claimed to have a breed of its own, the greatest distinctions that could be drawn were in colour, shape of horn, and perhaps size. Between the haphazard methods of breeding and poorness of feed all sank to a poverty line, and were brought to a low and equal level of comparative uniformity.

With better feed, especially during the winter months, it became possible to maintain the animals in thriving condition throughout the year. If the best of them were selected for breeding, new standards would be set up, and breeds defined. Enclosed pastures made it possible to select breeding material.

Bakewell was not the first man to take advantage of these new developments, but he was one of the most distinguished. Being the tenant of enclosed fields, and having the natural flair that is the most valuable possession of a livestock breeder, he was able to produce an outstanding race of Longhorn cattle, of New Leicester sheep and 'black' horses. The economic conditions of the time, too, encouraged his efforts, as those of others, because there was a rising demand for the meat-producing animal.

Of necessity Bakewell was an empiricist, but he was of an original cast of mind, and Prof. M. McG. Cooper, who contributes to this book a modern evaluation of Bakewell's work, estimates that his ideas were well over a century in advance of his time. So far as can now be learned, the main principles of Bakewell's breeding system was a degree of in-breeding which some have thought excessive, combined with what is now known as the progeny test, something largely neglected in the intervening century and a half. The results were so remarkable that Bakewell earned an international reputation in his own lifetime, and was sought out by visitors from all over the world. He could not, of course, have explained what he did in terms of modern genetical science, but he used the observed results of careful experiments. No doubt intelligent farmers had been in the habit, when they could, of selecting their best animals to breed from in the hope that like begat like, but Bakewell led the way towards modern breeding. His new water meadows added to his supply of 'natural' feeding stuffs. It is unfortunate, as Prof. Pawson says, that his records, if he ever kept any other than in his memory, have vanished, and that little is known of his early life. Nevertheless, this book forms a welcome addition to our knowledge of one of our greatest farming pioneers. The fact that it adds little to an exposition of his methods in a more explicit manner is no fault of the author; the necessary evidence does not, in fact, exist.

G. E. Fussell

PRINCIPLES OF ANALYSIS

Quantitative Inorganic Analysis

By Prof. G. Charlot and Denise Bézier. Translated by Dr. R. C. Murray. Pp. x+691. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1957.) 84*s*.

THE chief aim of this unusual book seems to be to stimulate an interest in fundamental principles rather than to provide detailed descriptions of reliable analytical methods. The authors state that their book is no replacement for specialized works.

In the first half of the book the theoretical aspects of chemical analysis are emphasized, particularly in relation to physico-chemical methods: the thirty-three chapters deal with a variety of subjects, including not only those usually found in works on chemical analysis but also, as examples, with statistical methods, determinations in solvents other than pure water, electrography, coulometry, and the use of radioactivity in analysis. Some practical details are included, though the treatment of some subjects, such as emission spectrophotometry, is very brief and the reader is left to use the many references provided.

Part 2 of the book deals with the determination of sixty-five of the chemical elements and contains much succinct information, though here again the practising analyst will often need to refer to the many original papers and specialized books listed.

The authors have attempted to provide comprehensive, though sometimes very brief and uncritical information and some blemishes are inevitable. As examples, one would hesitate to rely on ferrous ammonium sulphate for the standardization of dichromate, and one wonders why on p. 480 the gravimetric determination of manganese as pyrophosphate is omitted, while the poor method based on weighing as trimanganic tetroxide is mentioned. There is no mention on p. 546 of the gravimetric method for the determination of potassium based on weighing platinum after a chloroplatinate precipitation. One is surprised to read on p. 392 that the determination of bromide in the presence of chloride is difficult; no mention is made of the work of Haslam *et al.* (*Analyst*, 75, 343; 1950).

However, despite its defects, the book should encourage the student of analytical chemistry to strive for a better understanding of his work and to explore the possibilities of new methods.

C. O. Harvey

REASON AND CONTROVERSY

Methods and Criteria of Reasoning

An Inquiry into the Structure of Controversy. By Rupert Crawshay-Williams. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. viii+296. (London: Routledge and Kegan Paul, Ltd., 1957.) 32*s*. net.

AS its somewhat pretentious title indicates, this book deals with the various ways in which disagreements and controversies arise, and in which they can be resolved. Much of the argument expounds and applies ideas that have dominated recent philosophy; unfortunately it is conducted in a repetitious manner, and in a terminology that does not conform to the standards of precision which it, itself, desiderates. Some good points are made on the way, particularly concerning that fashionable shibboleth 'ordinary language'. Mr. R. Crawshay-Williams explicitly confines himself to what he calls 'testable' statements; he is not concerned with those which lack a decision-procedure for their truth or falsity, although he rightly says that these may be illuminating or interesting in some ways. This restriction of topic, quite legitimate in itself, involves a notion of testability which is too *simpliste*. It is baldly asserted, on p. 258, that the only kind of evidence that can be adduced for any belief is 'scientific' evidence; this view, which recalls the logical positivism of the 'twenties, now requires defence, and should not be taken for granted.

If the word 'science' is given such a wide meaning that it becomes vacuous, the principle is trivial; if used in its proper sense, the principle should be stated in a way that faces up to recent criticisms of the verification principle, contemporary developments in ethics, and, indeed, the existence of history as a form of knowledge. Crawshay-Williams's task is to show how, by redefinition and explication, we can render indeterminate, and hence controversial, statements into determinate and testable ones. He discusses examples of scientific controversy ('Are viruses molecules or organisms?', 'Is aphasia a pure or complex disorder?') in an interesting way which illuminates the conceptual tangles at issue, but which does not clarify or reinforce the main thesis. This is that the meaning of all descriptive statements is relative to both the context in which they are made, and to the facts in question. No description can be complete, or true, in itself, that is, out of relation to our cognitive interests; these determine the relevant area of fact, which in turn determines the truth or falsity of the description. Empirical discourse is described as a function of three variables: the subject matter (S), the description (D), and the context of the description (C). A complete analysis of an empirical statement is of the form 'S is D in C'; the correctness of a description depends not only upon facts but also upon the context in which it occurs. If Smith arrives 0·5 sec. before Jones, we correctly say that they arrived 'at the same time' in the context of a party, but it would be wrong to say that they had dead-heated in the context of a race.

This is important and true, but Crawshay-Williams's account of it is not satisfactory. Misgivings can be indicated only briefly. (1) It is assumed that empirical assertions are descriptions; this is not so, because existential statements, which are certainly empirical, are not descriptions, and only in rare cases are they dependent on context ('Is there a ghost in Hamlet?'). Ordinary existential statements like 'There is a fox in the covert' seem to be complete, and true or false, without reference to context. (2) The words 'sentence' and 'statement' are used as if they were synonymous, or nearly so; there is a mistake here, and it leads Crawshay-Williams into muddles. He distinguishes between sentence-token and sentence-type (p. 213), statement and statement-type (p. 72–3), and sentences and propositions (p. 85). The relations between all these are not explained, and hence there is an obscurity at the heart of the argument. (3) The words 'context' and 'criterion' are distressingly vague. The former is used to mean both 'universe of discourse' and 'purpose', while it is not clear whether 'criterion' is used to refer to the truth or to the meaning of a statement. It is regrettable that a book in this well-known series should contain elementary mistakes of grammar; three sentences conclude with the phrase "being paid attention to". C. K. Grant

A NEW APPROACH TO ELECTRICITY

Currents, Fields, and Particles

By Prof. Francis Bitter. Pp. xiv+600. (Cambridge, Mass.: Technology Press of the Massachusetts Institute of Technology; New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1956.) 68*s*.

This excellent book represents the second-year work of a two-year course developed by Prof. Bitter at the Massachusetts Institute of Technology, and "based on atomic physics". Sorted out into a more traditional sequence, the contents are similar to those of many books on electricity and optics available for this level, and the standard is at least as high. The arrangement and presentation are strikingly original, for the author has woven modern ideas into the whole of the book, so that the reader assimilates them as he goes through it instead of colliding with them towards the end. The general attitude of the author is like that of R. W. Pohl, to whom indeed he pays tribute, and the work carries the same persistent challenge to think in terms of fundamental physics as Pohl's books did nearly thirty years ago.

The first four chapters centre on the electric field and the electrical structure of matter, ionic and electronic conduction, and the detailed behaviour of dielectrics. It is interesting here to see how fully Rutherford's experiments on α-particle scattering, and, later, various uses of the RC circuit are discussed; these embody most important points of principle. On the other hand, the oscilloscope, the Van de Graaff machine, the linear accelerator, and other rather technical applications are indicated or outlined only. The main object, the study of the interaction between electric field and charged particle, is pursued firmly without digression.

The magnetic field is introduced (after a brief discussion of the unreliability of the magnetic dipole as a test object, and the rather too recent discovery of the utility of the proton for this purpose) in terms of the force experienced by a moving charge. The experimental justification for this is that the cyclotron, the velocity-selector, and measurements of e/m are known to work. Here the more elderly reader, who has after a struggle abandoned magnetostatics and accepted Ampère's experiments as a starting-point, is made to think very hard. Prof. Bitter is quite clear about the two main difficulties to be resolved. First, that the force between two current-carrying conductors is a very different matter from the force between two charged particles in motion; and also that we have no direct experimental knowledge about the field due to a single moving electron. He writes down the expression for the field due to a moving charge, and states that this is *consistent* with all experiments done using current-carrying conductors. This seems quite a revolutionary approach; but after all, only one sound experimental link between charged particle and magnetic field is really needed, and the rest is a deductive chain. It is unlikely that teaching laboratories will ever replace their current-balances by cyclotrons, and of course the author's treatment does not imply this kind of thing. The point is that the basic concept is taken to be the interaction between magnetic field and charged particle, rather than the force between pole and pole or between circuit and circuit. The determination of the ampere is explained clearly; and this chapter can be particularly commended for its presentation of what is at all levels one of the most difficult matters to teach.

From the next three chapters, on electromagnetic induction, electrical oscillations and electromagnetic waves, a few instances only need be given of their quality. The detailed treatment of the energy relations in an inductor, the very full account of the Hall effect, and the opportunity taken in the section on resonance to explain electron resonance and nuclear magnetic resonance in materials, are examples.

It would seem logical, and a great economy of effort, to treat light after the general properties of electromagnetic radiation have been mastered. Chapters 9 and 10, which deal with geometrical and physical optics, respectively, at first seem rather too elementary, for the electromagnetic theory is not, in fact, employed. But these chapters fit into the pattern of those that follow, when spectroscopic evidence for the location of energy-levels, the diffraction of particles, the black-body spectrum, and other topics requiring a background of optical knowledge appear. The beautiful frontispiece, of spectra taken using a grating crossed with an échelle, is, incidentally, not explained until the appendix.

The final chapters, starting with a review of the experimental basis of atomic physics, cover wave mechanics, atomic structure and nuclear physics.

The problems at the ends of the chapters themselves make interesting reading, ranging from calculations on the Massachusetts Institute of Technology cyclotron magnet and the interpretation of tables of experimental results to some very searching tests of a student's capacity to handle complicated data.

The book can be recommended with enthusiasm as an outstandingly clear explanation of fundamental principles in present-day terms. G. R. Noakes

THE SOLAR CORONA WITHOUT AN ECLIPSE

Die Sonnenkorona

Von Prof. M. Waldmeier. Band 2: Struktur und Variationen der Monochromatischen Korona. (Lehrbücher und Monographien aus dem Gebiete der Exakten Wissenschaften. Astronomisch-Geophysikalische Reihe, Band 5.) Pp. 353. (Basel und Stuttgart: Birkhäuser Verlag, 1957.) 68.50 francs; 68.50 D.M.

SINCE the early 1930's a number of astronomers have followed Lyot in making regular daylight observations of the solar corona from suitable mountain-top observatories. Prominent among these has been Prof. M. Waldmeier, director of the Federal Observatory at Zurich, and to-day an acknowledged expert in this field. For nearly twenty years he has carried out an extensive programme of such measurements, working at his Observatory's mountain station above Arosa, and this is the second of a series of three books describing the results. The first two books are confined to little more than a description of the apparatus, the methods, and measures; the third will discuss the physics of the corona, presumably in a much more general way.

Since there is often misunderstanding among those without special knowledge of this subject, it may be well to emphasize that normal coronagraph observations, including Prof. Waldmeier's, do not go more than about 5 minutes of arc from the edge of the Sun's disk. Even with the most advanced electronic devices there is at present no possibility of measuring optically in broad daylight to more than a radius, say, 10–15 minutes of arc, from the solar limb. For everything beyond a few minutes of arc, out to the zodiacal light region, 25 deg. or so away, we must rely still on total solar eclipses and on radio astronomy.

This volume, then, relates to the inner corona only, but within this restricted region the amount of information provided is very considerable. Perhaps the most important feature of Prof. Waldmeier's work is that he has observed systematically, with as standardized a procedure as possible, over more than a whole sunspot period. This second volume concentrates on the brightness distribution within the corona in the light of a few bright spectrum lines, especially the green line, 5303A. of [Fe XIV], and the red line, 6374A. of [Fe X]. These lines are not only the most convenient to measure; their considerable difference in ionization-level means that the relative behaviour of the two gives us valuable information on temperature and electron-density variations.

Prof. Waldmeier provides us lavishly with tables and diagrams, so that we may follow easily the large changes in brightness and shape of the corona through the sunspot cycle, and may see also the close local relationship with sunspots and faculæ. A great deal of the work rests on simple intensity measurements at a given height in the corona, but in addition there are estimates of the greatest height to which the corona could be detected against the sky and a number of measures of isophotes in 5303A. light, made using the 5350A. line from a thallium lamp for comparison. A series of sketches of coronal condensations are also given. These are somewhat rarer phenomena, usually with a life-time not exceeding one hour, and are associated with large, active, sunspot groups, and with typical spot prominences.

Apart from the condensations, however, most of the coronal structure revealed in this work seems to be rather stable, with relatively small changes during intervals of a fortnight. It thus becomes possible, from what we see projected on the sky around the Sun, to construct a first approximation to the three-dimensional corona and to compare what we get with the activity on the photosphere beneath, although the spots, faculæ, etc., by which this activity is assessed are observed near the centre of the disk, separated by a week from the related measurements of the corona. The book gives many charts with comparisons of this kind.

This is very much an individual work. The measurements appear to have been made entirely by the author, single-handed. Literature references are to the author's papers exclusively, and little attempt has been made here to relate the observations to investigations by any other astronomer. Presumably a more general discussion and synthesis will come in the third volume. Meanwhile we have in this and the first volume an impressive collection of measurements, of great importance for anyone who wishes to become better acquainted with the still poorly understood outer atmosphere of the Sun.

R. O. Redman

LOW-TEMPERATURE PHYSICS

Handbuch der Physik

Herausgegeben von S. Flügge. Band 14: Kältephysik I. Pp. vi+349. 72 D.M. Band 15: Kältephysik II. Pp. vii+477. 112 D.M. (Berlin: Springer-Verlag, 1956.)

TO find, in an encyclopædia of physics running to fifty volumes, that two should be devoted specifically to low-temperature physics raises the question whether nowadays it is a sufficiently distinct branch to justify separate treatment. Perhaps before the War an affirmative answer could have been given; only a few laboratories were equipped to handle liquid helium, and they confined their attention almost exclusively to phenomena occurring at the lowest attainable temperatures. This attitude still persists in some laboratories, particularly the larger cryogenic laboratories in Europe, but it is beginning to seem a little out of date now that liquid helium is so readily available and its specialized techniques so easily assimilated. A more realistic taxonomy of physics is one which accepts solid-state physics as a major subdivision, comprising a wide variety of topics such as metals, semi-conductors, dielectrics and magnetic materials, and perhaps incorporating the liquid state into honorary membership. In this classification cryogenics is relegated to a comparatively humble office as one out of many useful techniques, and this is surely as it should be. Electrical conduction at low temperatures is not, one hopes, to be sharply distinguished from electrical conduction at room temperature and upwards; and as our knowledge increases we may expect to see superconductivity (usually quoted as a typical low-temperature phenomenon) fit into place as but one aspect of the behaviour of metals. Similarly, although the interest of liquid helium essentially is derived from the fact that it remains liquid down to the lowest temperatures, its ultimate importance to physics does not so much lie in this as in the light it throws on the liquid state in general, and the fact that it provides both stimulus and critical tests for fundamental theories of the condensed state of matter.

Thus the editorial policy which has singled out low-temperature physics for special treatment has encouraged the authors to take a narrow view of their topics, and unfortunately several of them appear to have accepted this limitation of their scope with something like enthusiasm. Indeed, so much labour has obviously gone into these exhaustive compilations of facts that it may seem ungrateful to complain that the total effect is one of deplorable dullness. Yet there is indeed only one article, that by J. Bardeen on the theory of superconductivity, which can really be said to be exciting; and this is distinguished from the rest chiefly because the author is not content to act as an impassive recorder of what is known, but is eager to explore those regions where the meaning of the observations is obscure. It might perhaps be contended that speculation is out of place in this sort of ponderous compendium; but surely the reader may be permitted to expect a mite of imagination in return for the very stiff price he must pay. All too often we have in these articles the mere body without a breath of the quickening spirit, and £8 a volume is too much to ask for a sarcophagus of physics.

A. B. PIPPARD

NORTH AMERICAN SNAKES

Handbook of Snakes of the United States and Canada

By Prof. Albert Hazen Wright and Anna Allen Wright. Vol. 1: Pp. xviii+564. Vol. 2: Pp. ix+565–1106. (Handbooks of American Natural History.) (Ithaca, N.Y.: Comstock Publishing Associates (Division of Cornell University Press), 1957.) 14.75 dollars the two volumes.

HERPETOLOGISTS must form a very small percentage of the population, for the aversion and horror inspired by snakes in the ignorant is very widespread. "Because of his fear, his agricultural practices, his livestock, and his vehicles, man is the worst enemy of snakes. From senseless fear man kills beautiful small ringnecks and useful large rodent eaters with a wantonness hardly believable." But it will be a long time before he stops blindly following the biblical injunction to crush under the heel the allegorical satanic serpent. This exhaustive work gives an account of all the species of snakes found in the United States and Canada, and forms a valuable handbook for herpetologists everywhere but particularly for those of the North American continent. Gathering material for this book has occupied the authors for many years, during which they have examined, handled and photographed living examples of nearly all the species and subspecies, so that their descriptions are fully authoritative.

An introductory chapter of thirty-one pages explains the plan of the work, and discusses the various topics considered under each species. The authors point out that until recently the emphasis of herpetologists has been almost solely taxonomic, and that other aspects of the subject have been studied more or less incidentally, "for example, most of our life-history studies are of captive specimens in our zoos". The primary purpose of this book is to present the living animal, but "herpetology needs field studies of life-histories, food, movements, habits, general ecology, associations, and colour phases". The introduction includes maps showing the ranges of important plants, structural geology, forests and trees, the physical divisions of the continent, and the vegetation regions. These are most useful when used in conjunction with the numerous maps showing the range of individual species of snakes; "the types of rock masses together with the temperature and rainfall control the varied vegetative areas of the country and these in turn control the food and shelter on which the animal is dependent. We can to some extent associate certain species with distinctive soil and vegetative areas". Several pages deal with courtship and reproduction, and include an account of the varied and often bizarre surface anatomy of the hemipenis. Finally, the authors "urge young naturalists to keep journals", advice that cannot be too strongly emphasized. They note that both voluminous writers and "reticent superb field men, such as W. DeWitt Miller, have religiously recorded their observations", and rightly say that these notes prove "very useful, however good your memory may be". They might have added that even the best memory is unreliable for details, and that notes taken immediately are essential to any serious study.

The description of each species and subspecies is divided into sections: vernacular names, range, size, distinctive characters, colour, habitat, period of activity, breeding, food, field notes, and authorities. Each section is divided under various subheadings as information may be available. The nomenclature followed is mainly that of the second edition of Perkins' "Key to the Snakes of the United States" and of the sixth edition of Schmidt's "Check List of North American Reptiles". The illustrations are a special feature of the book—distribution maps, line drawings of anatomical details and scale patterns, and above all the photographs. The last show dorsal and ventral views of the whole animal, and larger views of the head and sections of the body, often in dorsal and ventral, as well as lateral, view, nearly always taken from the living snake.

The pagination of the work runs continuously through the two volumes, the second of which concludes with a glossary and a copious index. There is a select bibliography of general works on North American herpetology and of check lists. Although the work appears to be complete in two volumes the introduction to the select bibliography states that the complete bibliography will appear in Volume 3; this is the only reference to a future third volume.

DAMAGE TO SOLIDS BY LIQUID IMPACT AT SUPERSONIC SPEEDS

By Dr. F. P. BOWDEN, C.B.E., F.R.S., and J. H. BRUNTON
Physics and Chemistry of Solids Laboratory, Physics Department, Cambridge

A DROP of liquid striking against a solid surface at high velocity may produce considerable deformation and damage. Such damage can occur on the surfaces of aircraft during high-speed flight in rain; in this form it is referred to as 'rain erosion'[1]. Since 1945, when the problem of rain erosion first became apparent, its seriousness has increased enormously with increasing speeds of aircraft and missiles. Investigations into the mechanism of rain erosion have been carried out in the United States by Engel[2], and in Great Britain by Jenkins[3].

We are making a study in this Laboratory of some of the basic aspects of liquid/solid impact at very high speeds. For this purpose a simple apparatus has been developed for projecting a small cylinder of liquid against a stationary solid surface. The cylinder is normally about 1 mm. in diameter and 2 cm. in length, the mass of liquid involved being approximately equivalent to that of a large raindrop. Impact velocities of up to 3,500 ft./sec. have been obtained. Under such conditions even the hardest surfaces will become deformed.

Briefly, the apparatus consists of a small stainless steel injector into which about 0·01 c.c. of liquid can be sealed by a neoprene disk. At the instant of firing, a slug from a high-power air rifle rams the disk into the injector. The highly compressed liquid escapes through a nozzle at the far end of the injector as a short high-velocity jet or cylinder. Information on the structure, velocity and behaviour on impact of the liquid has been obtained by the Cranz–Schardin system of high-speed photography using a six-lens camera designed by Dr. J. S. Courtney-Pratt. In this manner it was possible to obtain six pictures of various stages in an event over a period of 25 μsec.

Fig. 1 is a picture of a water jet of 1 mm. diameter produced by the apparatus and moving in air. The nose velocity in this case is initially about 3,100 ft./sec. The structure of this jet can be regarded as typical of those produced by the apparatus. Air friction is responsible for the mushroom of spray at the nose of the jet; this type of break-up is quite small in the early stages of travel, but increases rapidly with distance. Because of this, target specimens are normally placed at a distance of ¼ in. from the nozzle. The cylindrical core of the jet maintains an approximately uniform cross-section along its length. High-speed photoelastic pictures indicate that only the core is responsible for inducing stress in the target material; the associated spray plays little part in the deformation process on impact. As a simplification then, the impact is considered to occur between a liquid cylinder and a plane specimen surface struck perpendicularly.

Deformation of Metals

An example of the type of deformation which can occur in a hard metal surface subjected to the impact of a water cylinder is given in Fig. 2*a*, together with the surface profile of the region in Fig. 2*b*. The metal in this case was a high-strength stainless steel. The main effect of the impact is to produce a shallow saucer-shaped depression in the surface, with the two additional features of a central pit, and a highly deformed annular region just inside the rim of the depression. The area of deformation corresponds closely to the area over which the spreading cylinder exerts a pressure; this is, of course, considerably greater than its initial cross-section. The pressure is assumed to be a maximum under the centre of the collapsing cylinder, and to fall smoothly to zero at points where the liquid flow first becomes entirely parallel to the surface. These positions can be determined from photographs taken during the impact. Such a pressure distribution on the surface would give rise to a depression similar to that in Fig. 2*b*. For comparison, the depression formed in aluminium under the same conditions is shown in Fig. 2*c*; the area of the surface affected is the same, but the depression is more than ten times as deep. The central pit in Fig. 2*a* and *b* is probably due to the effect of the very high pressure in this region on an already existing flaw or pit in the surface. Such a pit acts as a stress raiser favouring further localized deformation. In a soft metal this effect may be masked by the large overall flow.

The annular region of heavy deformation at the edge of the impact zone in metals has the appearance of having been sheared open by water flowing at very high speeds over it. The deformation marks consist of alternate ridges and depressions running parallel to the rim; in soft metals, flow channels are apparent in the depressions, indicating the manner in which metal has been sheared out to form the ridges. Such

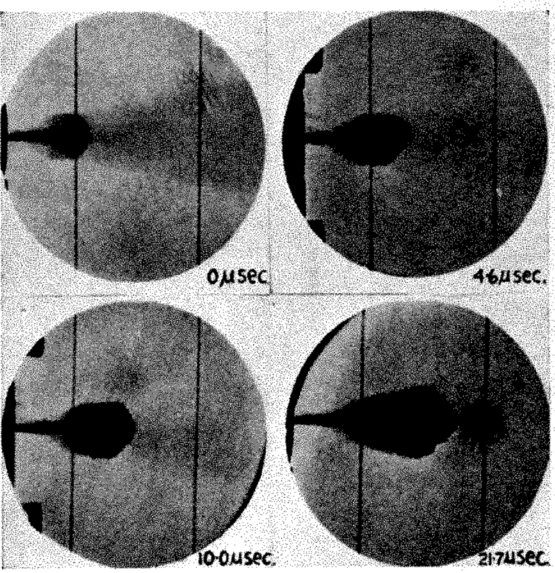


Fig. 1. A series of four frames selected from a group of six showing a water jet moving in air at an initial velocity of 3,100 ft./sec. The jet is travelling from left to right across two vertical marker wires 1 in. apart. The timing of each frame with respect to the first is shown in microseconds

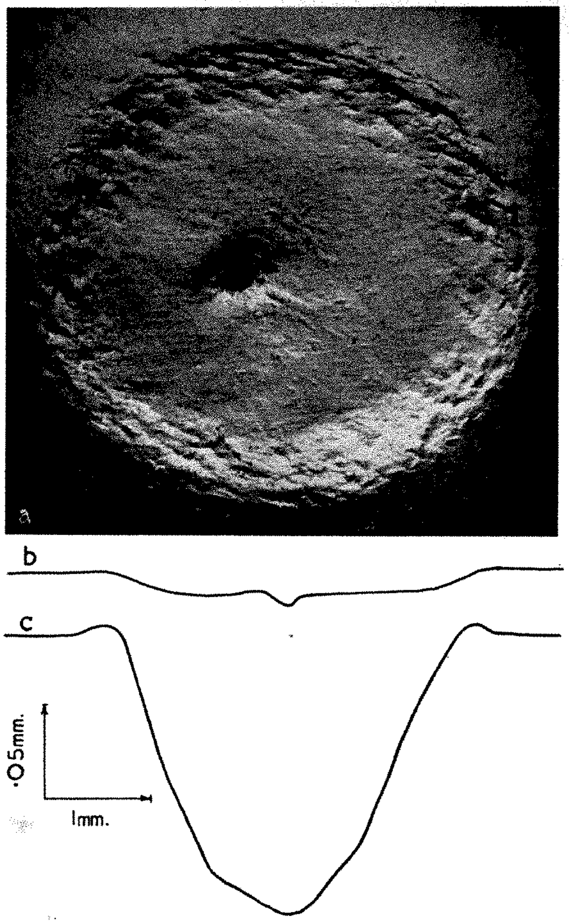

Fig. 2. (*a*) Deformation produced in a stainless steel surface by the impact of a single water jet at 2,500 ft./sec. The surface contour of the deformed region is given in (*b*), and for comparison the deformation of aluminium in (*c*)

a shear deformation of the surface would be most likely to occur at the boundary of the impact zone, where the velocity of the surface flow is greatest. If a shear mechanism is responsible for the rim deformation, then this deformation would be expected to depend upon the viscosity of the liquid. Using aluminium targets and water/glycerol mixtures as the deforming liquid, the intensity of the deformation near the rim was found to increase with the viscosity.

Deformation of Non-Metals

The failure pattern due to liquid impact in rigid plastics, glasses and ceramics is quite different from that observed in metals. 'Perspex' was found to be a convenient material in this group to work with; besides being transparent, it has the additional advantage that the state of stress in it during impact can be studied simultaneously by a photoelastic method.

Fig. 3 illustrates the surface damage in 'Perspex' due to the impact of a water cylinder at 3,000 ft./sec. The main feature of the damage is a ring crack. The area of the surface inside the ring is undamaged, and for a considerable distance outside the ring the surface is pitted with short straight circumferential cracks. The star crack which can be seen in the centre of the photograph is below the surface.

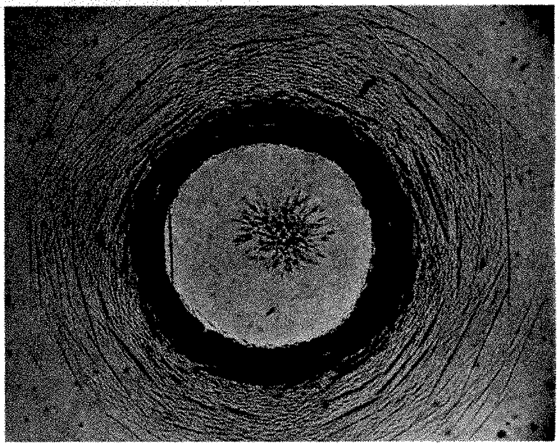

Fig. 3. Surface deformation in 'Perspex' due to the impact of a water jet at 3,000 ft./sec. The ring-crack has a mean diameter of 3·5 mm. The central star crack is beneath the surface

Fig. 4 is a cross-section through an impact zone in 'Perspex'. The central subsurface cracking consists of fracture planes lying approximately normal to the surface. The ring crack as seen in section meets the surface at an angle. Ring cracks produced at impact velocities of less than 2,000 ft./sec. often do not cut through to the surface. When this occurs, an annular depression remains in the surface above the crack; probably the presence of the crack facilitates permanent deformation of the area above it.

The effect of repeated impact on 'Perspex' is shown in Fig. 5. The surface profiles were obtained using a 'Talysurf' machine. The general behaviour is one of widening of the ring crack together with a spreading of subsurface cracks. After four or five impacts, the various fracture surfaces join up, and a large piece of 'Perspex' is dislodged from the surface.

As in the case of metals, failure in 'Perspex' can be thought of as arising primarily from the distribution of pressure under the jet, together with the deformation associated with rapid flow along the surface. Brittle failure may be expected to occur preferentially on planes across which the tensile stress is a maximum. The Hertz theory[4] of contact stresses can be used to predict the regions of high tensile stress in the 'Perspex' for the given distribution of pressure on the surface. Bearing in mind the limitations of the theory when applied to impact problems, it is possible to deduce that the maximum tensile stress occurs at the surface across the circular

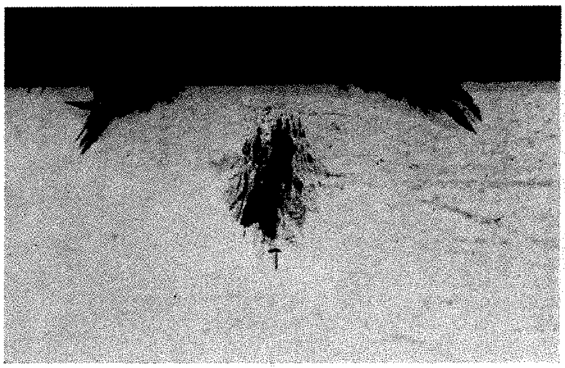

Fig. 4. A cross-section taken through an impact zone similar to that shown in Fig. 3. The shape of the ring-crack and the central zone of subsurface cracking can be clearly seen

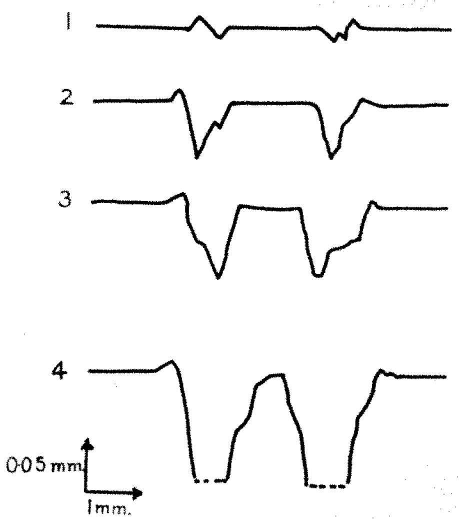

Fig. 5. The effect of 1, 2, 3 and 4 impacts of a water jet at 2,000 ft./sec. on the surface contours of 'Perspex'. The damage is seen to be concentrated in the ring-crack; the central region remains comparatively intact until massive breakdown occurs

boundary defining the limits of the area under pressure. Outside the boundary the tensile stress decreases slowly with distance; inside the boundary it falls abruptly to zero and becomes a compressive stress. Such a stress distribution accounts effectively for the pattern of surface cracking. The theory also predicts that the ring crack should form part of a conical rather than cylindrical surface.

Similarly, the tensile stress across the central axis normal to the surface attains a maximum value a little way below the surface; such a stress would explain the vertical planes of subsurface fracture in Fig. 4. The rapid surface flow accentuates these types of failure by opening up the fracture planes in the direction of flow, and in this way material is chipped from the surface.

Scabbing of the Back Surface

If the specimen is thin, a large scab may be detached from the back surface when the front surface is struck by the liquid. Fig. 6 shows this effect in a $\frac{1}{4}$-in. thick 'Perspex' plate. In this case, the top surface which has been struck has the normal ring crack, and the lower surface has developed a scab.

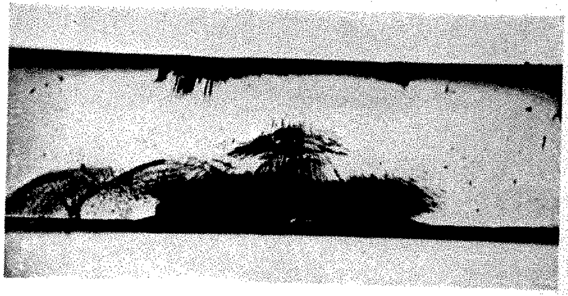

Fig. 6. Scabbing of the lower surface of a $\frac{1}{4}$-in. thick 'Perspex' plate. The velocity of the jet striking the upper surface was 3,000 ft./sec. The central zone of cracking in the body of the plate indicates a tendency to form a secondary scab, and illustrates the manner in which the reflected tension wave pulls the material apart

The compression wave set up on impact is reflected from the back surface as a wave of tension, and the associated tensile stress effectively pulls a piece out of this surface. The new surface so formed reflects the remainder of the compression wave, and the process of scab formation tends to be repeated. An attempt to form a secondary scab is shown by the cluster of cracks in the centre of the plate.

The fact that the impact of a water cylinder with a velocity of 3,000 ft./sec. can deform materials as hard, for example, as tungsten carbide is not surprising if it is realized that the pressure developed on the surface by the liquid is well above the yield strength of most common metals. The associated stress may be further magnified by the presence of surface pits. In addition, there are the shear stresses associated with the high-speed flow of the collapsed cylinder over the surface. Flow velocities parallel to the surface were observed to be two to three times as great as the impact velocity. Any surface irregularity in the path of this flow would certainly be deformed.

Since the present-day tendency is towards air travel at very high speeds, it is clear that an understanding of the mechanism of deformation processes at these speeds is desirable.

We are grateful to Dr. D. Tabor for helpful discussions during this work.

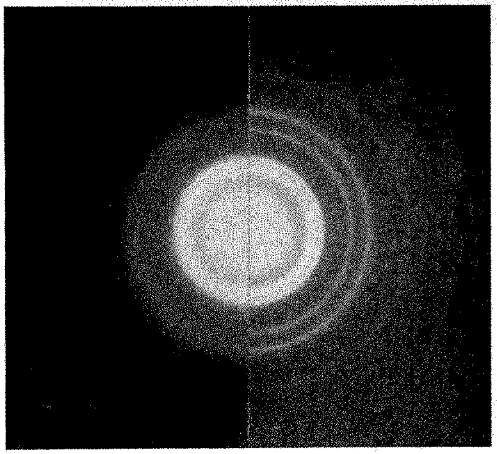
SIMULTANEOUS EVAPORATION OF PLATINUM AND CARBON FOR POSSIBLE USE IN HIGH-RESOLUTION SHADOW-CASTING FOR THE ELECTRON MICROSCOPE

By D. E. BRADLEY
Associated Electrical Industries, Ltd., Aldermaston

CONVENTIONAL methods for shadowing electron microscope specimens[1] have one grave disadvantage: the resolution obtained is seriously limited by the aggregation of the shadowing material into discrete crystallites. In the case of the much-used gold/palladium alloy, these particles may measure as much as 40–50 A. in diameter. Materials such as platinum and uranium, which are used where a higher resolution is required, form particles of about half this diameter. The resolution and quality of the resulting electron micrographs are limited accordingly. A few non-crystalline materials can be deposited by vacuum evaporation; among them are carbon[2] and silicon monoxide[3]. These materials produce sharp shadows, but their electron-scattering power is low, so that films of the order of 50 A. in thickness are



a *b*

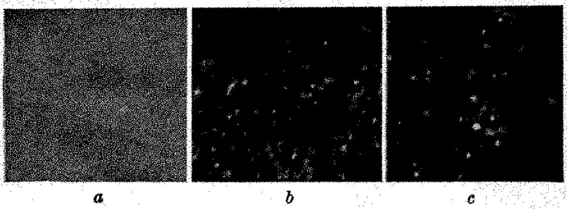
Fig. 1. Electron diffraction patterns of a platinum/carbon film: *a*, under normal operating conditions; *b*, recrystallized with very heavy electron bombardment (accelerating voltage 70 kV.)

required to obtain reasonable contrast. This thickness causes a loss in resolution due to 'pile-up' on the specimen[4], resulting in the distortion of its shape.

Clearly, a shadowing material of high atomic number, which does not form aggregates, is required. Aggregation must not occur either during deposition or under the influence of the electron beam. It has now been found that the simultaneous evaporation of a heavy metal and carbon produces a film with the required properties. Several metals have been tried, and the most suitable found so far is platinum.

The technique described here for achieving the simultaneous evaporation avoids the difficulties which would be encountered if two separate sources were employed. It is based on the method used for the evaporation of carbon alone[1]. Instead of pure carbon electrodes, however, rods containing a high percentage of platinum (about 85 per cent w/w) are used. These rods are prepared in the laboratory by an experimental process which involves bonding together the two constituents in powder form. The rods are pointed by means of emery paper and mounted in metal holders. A weak spring is fitted to hold the points together *in vacuo*. On passing a heavy current, resistance heating at the points causes carbon and platinum to evaporate together. The resulting film, even when thin, is strong enough to form a self-supporting replica. It can, of course, be deposited on previously prepared specimens in the normal way.

As deposited, the films are substantially non-crystalline. This can be seen from the halos of the electron diffraction pattern shown in Fig. 1*a*. When a dark-field image, selected from the brightest halo by means of the objective aperture, is examined, no discrete crystallites can be detected (Fig. 2*a*). It has been found that this dark-field test is extremely sensitive. The film is completely stable under illuminating conditions used for very high resolution work (instrumental magnifications of 40,000–60,000) in the experimental Metropolitan Vickers *E.M.*6, as developed in the Associated Electrical Industries Research Laboratory[5]. Granulation of the platinum only occurs under electron bombardment many times more intense than is required for normal operation. Fig. 1*b* shows a diffraction pattern obtained from a film which has been deliberately recrystallized in this way. The sharp rings of platinum indicate fairly large crystallites, and these are shown clearly under dark-field conditions, selecting the two bright inner rings (Fig. 2*b*). Evaporated platinum metal is shown under similar dark-field conditions for comparison (Fig. 2*c*). The electron diffraction pattern is similar to that shown in Fig. 1*b*.



a *b* *c*

Fig. 2. Dark-field electron micrographs (× 100,000) of: *a*, platinum/carbon film; *b*, platinum/carbon film recrystallized as in Fig. 1*b*; (*c*) evaporated platinum metal on a carbon film

The platinum/carbon ratio of the deposit has not been measured; but comparison of the composite film with carbon films of equivalent thickness in the electron microscope indicates that the platinum content is high.

The preliminary examination of platinum/carbon shadowed surfaces in the electron microscope suggests that the method is extremely promising for high-resolution shadow-casting. Typical results are shown in Figs. 3 and 4. An important point, the production

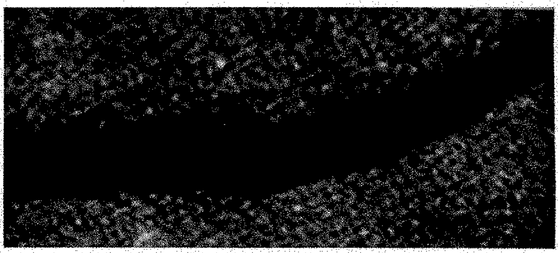


Fig. 3. Platinum/carbon replica (deposited at 45°) of an edge of a methyl orange crystal. (× 250,000)

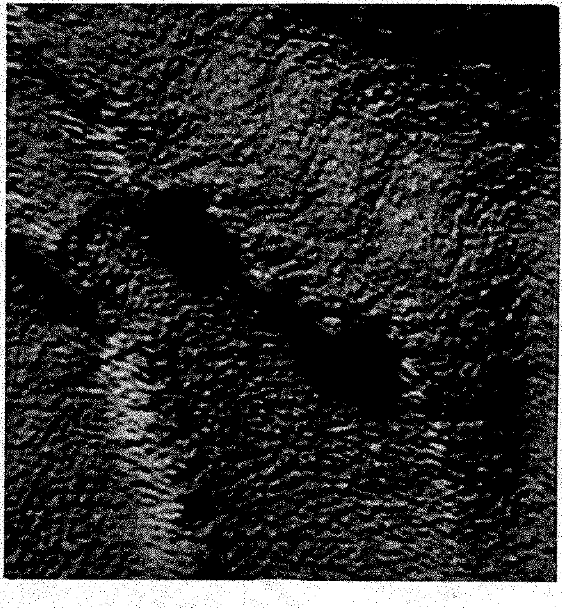

Fig. 4. Platinum/carbon replica (deposited at 45°) of a cleavage surface of a sugar crystal. (× 250,000)

of extremely sharp shadows, is illustrated in Fig. 3, which shows a platinum/carbon replica of an edge of a crystal of methyl orange. It is interesting to note that this shadow was obtained using a target distance of only 2·5 cm. (the distance for evaporated metal is 8–15 cm.), indicating a point source. It will be appreciated that there is a direct relationship between sharpness of shadows and resolution.

The potentialities of the method can be estimated from Fig. 4, which shows a platinum/carbon replica of the surface of a sugar crystal. It can be stated conclusively that the background structure is not due to the granulation of the shadowing material. The reasons are: (1) that the structure varies considerably over the surface; (2) that diffraction and dark-field tests, applied as a control to each specimen, indicate the total absence of any granularity. A close examination of the original plates shows that this structure consists of minute protrusions some 20 A. in width. This work will be published in greater detail elsewhere.

I wish to thank Dr. J. S. Halliday for his valuable advice, and also Dr. T. E. Allibone, director of the Research Laboratory, Associated Electrical Industries, Ltd., for permission to publish this article.

PROCESSING OF FOODS WITH IONIZING RADIATIONS

MUCH attention has been aroused in recent years by the possibility of using ionizing radiations in preserving foods. Serious investigations started about ten years ago, although the idea itself is considerably older. While it has been found quite feasible to sterilize foods with radiation, some undesirable changes usually accompany the process. Such changes depend markedly on the way in which the food has been treated, and research has been particularly directed towards finding the precise conditions which give the best products. The possibilities and limitations of the method were discussed at a symposium held at Cambridge during September 26–27. About twenty foreign visitors were among the hundred and twenty who attended, and the two principal British laboratories working in this field—the Low Temperature Research Station, Cambridge, and the Technological Irradiation Group, Atomic Energy Research Establishment, Harwell—were represented.

The main attraction in using ionizing radiations to preserve foods is that the amount of radiation energy required to eliminate all food spoilage micro-organisms raises the temperature of the irradiated food by only a few degrees; the preservation of food in the raw state is therefore possible. A major deterrent, however, is that the associated chemical changes, though small in total quantity, may have adverse effects on the quality of the food, and become evident as changes in the odour, flavour or texture. It is necessary, therefore, to find methods to minimize or mask these quality changes. Smaller amounts of radiation which are insufficient to cause noticeable changes can be used. Such treatments eliminate only a fraction of the micro-organisms present—the so-called pasteurization treatments—and additional treatment, such as heat or refrigeration, is necessary to prevent spoilage of the food due to the growth of the surviving micro-organisms. Some of the results obtained using these techniques were described at the symposium. In addition to these generally applicable methods, there are also uses where small amounts of radiation can be applied to achieve a more limited particular purpose, for example, to eliminate insects in grain or packaged foods, or to inactivate food-poisoning *Salmonella* organisms in frozen whole egg; these applications, too, were discussed.

Much of the work on the irradiation of foods has been carried out in the United States, and British work is best considered against the background of American investigations. The Quartermaster Corps of the U.S. Army has sponsored the majority of this work and, not unnaturally, much emphasis has been placed upon military uses. The possibilities for civilian applications have, however, been kept clearly in mind. The present state of the work was outlined in two American papers, one by A. W. Harvey, and the other by D. K. Tressler, B. H. Morgan, M. Simon and V. K. Peterson. The dose of radiation necessary to achieve 'commercial' sterility in foods is considered to be in the range 3,000,000–6,000,000 rads. A large number of foods have been examined after doses of this magnitude, and twenty-one have been considered promising. Objectionable flavours are usually found to decrease on cooking, and generally the flavour of the irradiated foods tends to improve after storage for several weeks or months at room temperature. To support the vast amount of laboratory tests being conducted on irradiated foods, extensive animal feeding tests are in progress. These, so far, have not shown any harmful effects due to irradiation. Limited human feeding tests have also been made, again without showing adverse effects; and troop feeding tests on a larger scale are planned. To provide adequate food processing and radiation facilities for supplying the necessary food, the U.S. Army intends to construct a food-processing plant equipped with gamma-ray and cathode-ray sources, each of which can treat about 1,000 tons of food per month. Much basic research is being carried out by contract with civilian laboratories. In many cases, where the contractor is interested in civilian applications, the emphasis of this work is on the use of low-dose treatments. The smaller quality changes produced in this way will probably be more acceptable to the domestic consumer, who sees the food at all stages in its preparation for the table.

In Britain also, more attention has been given to pasteurization procedures, since most of the research has been aimed at civilian exploitation. R. S. Hannan described some of the results of a detailed examination of the response of chicken meat towards irradiation under a variety of conditions. With doses of 2,000,000 rads or more, flavour changes were considered objectionable by most members of a taste panel;

with lower doses the degree of flavour change depended markedly on the conditions before and during irradiation, for example, its oxygen content, and whether it was frozen. Odour changes in raw minced chicken meat could be detected with doses as low as 50,000 rads, but if such samples were afterwards cooked by steaming most people could only detect adverse flavour changes if the meat had been given doses of 250,000 rads. Whole chicken carcasses responded rather better: after doses of 500,000 rads or more, flavour changes were only just detectable in the roasted birds. Margaret J. Thornley said that bacterial counts on the minced chicken irradiated with 250,000 rads showed that it could be stored at 5° C. several times longer than unirradiated control samples; lower doses produced only a slight increase in storage life. Whole chicken carcasses, packed in 'Polythene' bags and given 500,000 rads, could be stored at 3° C. for two to three times as long as control samples. The bacterial flora of irradiated chicken differed considerably from that normally observed. M. Ingram emphasized that selective elimination of some micro-organisms by irradiation could result in the eventual spoilage of the chicken taking an unusual course. Adequate refrigeration seems essential to prevent the growth of possibly harmful bacteria which might survive irradiation.

A number of techniques have been suggested for minimizing the radiation damage to foodstuffs. Thus, for example, a low dose of irradiation combined with some heat treatment may be useful to sterilize foods. Freezing of samples before irradiation usually makes flavour changes less apparent, and the presence or absence of oxygen during and after irradiation is important. The use of such devices is being actively investigated. A very promising approach is to combine radiation with antibiotic treatment. This technique was used by J. Liston and J. M. Shewan in some experiments on the irradiation of fish. Cod and lemon sole suffered little adverse flavour change after doses of 500,000 rads, and the storage properties under refrigeration were improved. A much greater improvement in storage properties was achieved, however, when this dose of radiation was given after the fish had been dipped in a solution of chlortetracycline.

The use of radiation to eliminate a specific harmful micro-organism was discussed in a paper by R. S. Hannan, J. Brooks and Betty C. Hobbs on the irradiation of frozen whole egg. This commodity, large quantities of which are imported into Britain, often contains *Salmonella* bacteria which cause food-poisoning. 500,000 rads, given to the egg in the frozen state, eliminates the *Salmonella*. The principal adverse change was a slight odour in the thawed raw egg, which was not usually detected in baked products made from the egg.

Another promising application is the use of radiation to eliminate insect infestation. This is easily achieved by preventing reproduction of the insects with doses up to about 20,000 rads. Two methods of control exist: sterilization of all the insects or swamping of the female population by releasing a large excess of radiation-sterilized males. P. B. Cornwell described some experiments on the elimination of grain weevils and flour mill moths, using doses in the range 10,000–20,000 rads. Direct killing of these insects requires doses about ten times larger than this. If the economics of the process are favourable, there would appear to be little objection to the disinfestation of grain by this method. H. G. Harvey and R. S. Hannan had examined the effects of low doses of radiation upon packaged foods (for example, cereals, dried fruits, etc.) to eliminate insects, and found that in nearly all the foods examined, doses of 40,000 rads produced no detectable adverse changes.

The use of radiation in the food industry naturally presupposes that adequate sources of radiation will be available. Not all types of ionizing radiations are suitable. Any which might induce radioactivity in the food would be unacceptable—this excludes neutrons and radiations of energy higher than about 15 MeV. Others are excluded because of low penetrating power or high cost. The most generally useful are gamma-rays, of high penetration, and cathode rays, with rather limited powers of penetration. S. Jefferson, speaking on radioactive sources, said that large quantities of fission products will eventually be available for gamma-ray sources. For a number of years, however, cobalt-60, and smaller quantities of cæsium-137, are likely to remain the principal sources. At present the supplies of these are limited. M. C. Crowley-Milling, dealing with electrical machines as sources of radiation, said that cathode-rays of suitable energy are readily obtainable from linear accelerators now manufactured in Great Britain. Against the limited penetration of cathode-rays are the advantages of easy focusing, their availability as and when required, and the high dose-rates obtainable. The cost of treatment can be calculated, and Mr. Crowley-Milling gave the following estimates: to treat foods with 1,000,000 rads costs 0·4*d.* per lb.; to treat potatoes with 10,000 rads costs 1*s.* 6*d.* per ton; and to treat grain with 50,000 rads costs 5*s.* per ton. These figures make due allowance for running costs, depreciation, percentage of energy utilization, etc., but do not include any handling costs. The costs of treatment with gamma-rays are more difficult to calculate, but, for some time at least, are likely to be higher than those quoted above. Costs of this magnitude do not appear to be prohibitively high.

Other topics discussed at the symposium included the prevention of sprouting of potatoes (papers from W. G. Burton and D. B. Powell); and, among the less-promising applications, the sterilization of milk (T. Horne), the prevention of mould growth in wrapped baked products (F. J. H. Ottaway), and the elimination of micro-organisms in damp grain (T. A. Oxley).

The intensive investigations of the behaviour of food on irradiation have shown many gaps in the knowledge of how non-irradiated food behaves. This has led to the initiation of much fundamental research, both in academic studies and applied technology. As enzymes are not completely inactivated by the amounts of radiation necessary for sterilization, it is important to know what action surviving enzymes might have on stored foods. The paper by R. Zender, C. Lataste-Dorolle, R. A. Collet, P. Rowinski and R. F. Mouton, of the Battelle Memorial Institute, Geneva, was therefore interesting, dealing as it did with autolytic changes occurring during storage of sterile muscle samples. It may be that some of the changes observed with irradiated meats may be due to autolytic processes rather than to radiation effects. Similarly, much research in radiation chemistry and biology has been stimulated. At the symposium, three papers were presented on radiation chemical aspects (by A. J. Swallow, B. Coleby and N. Uri), and a further paper dealt with some chemical effects in irradiated meat (G. M. Wilson). These contributions indicated that the theories of radiation chemistry are still far from adequate to explain the changes in such complex systems as foods. As R. S. Hannan pointed out, in nearly all cases, the easiest approach to a particular problem is an experimental one. In the microbiological field there is obviously need for more information on how micro-organisms behave on irradiation, and particularly on the behaviour of those organisms which survive irradiation. If, ultimately, the idea of processing food with radiation is not exploited, the results of such researches as that of the Quartermaster Corps of the U.S. Army on the properties of packaging materials will be of great value to the food industry.

It will still be necessary to show that irradiated foods are acceptable from the medical point of view, even if the process is considered useful to the food industry and the consumer. To yield information on this topic, animal feeding studies are being conducted at the Wantage Radiation Laboratory, and T. Horne gave details of these, and the plans for future work. The very careful and large-scale experiments being conducted by the Office of the Surgeon General of the U.S. Army should also be extremely valuable. To date, the tests have failed to show any harmful effects through eating irradiated foods. Some destruction of vitamins by irradiation has been noted but, in general, losses are no greater than with most other methods of food processing.

The symposium confirmed the impression that has been growing for some time, that radiation processing is unlikely to displace conventional methods of preservation. It does seem, however, that it will be a useful additional method, and there are clearly some applications of considerable potential use where it has special advantages. But, even with these, there still remains much more research to be done before the process can be exploited commercially.

A fuller account of this symposium is available on application to the Superintendent, Low Temperature Research Station, Downing Street, Cambridge (L.T.R.S. Memorandum 312).

This article has been prepared as part of the programme of the Food Investigation Organization of the Department of Scientific and Industrial Research.

OBITUARIES

Prof. R. M. Davies

Rhisiart Morgan Davies, professor of physics in the University College of Wales, Aberystwyth, died suddenly on February 18, a fortnight after his fifty-fifth birthday.

His death terminates one of the most interesting careers in the British university world. He was a native of the quarrying village of Corris, Merionethshire, and received his early education at the village school and at the grammar school at Dolgelley, where his scientific potentialities were recognized by Dr. John Griffith, one of the most remarkable of Welsh headmasters. In 1921 he entered the College at Aberystwyth, where he was destined to spend virtually the whole of his university career. He graduated with first-class honours in 1924, and was appointed assistant lecturer in 1925.

His research career may be said to have commenced at the Admiralty Signal School at Portsmouth, where he spent the summer of 1925 and where he was introduced to quartz crystals and piezoelectricity. On his appointment to the staff at Aberystwyth he entered upon a research programme on the elastic properties of Rochelle salt crystals, as determined both statically and dynamically. The circuitry of this problem led him to digress, at the instigation of a chemical colleague, into a determination of the absolute dielectric constant of pure benzene at low radio-frequencies; he also developed two types of moisture meter for use with granular materials, one of which was marketed commercially.

These various research projects were pursued with characteristic vigour and determination, and gained him in succession the M.Sc. and D.Sc. degrees of his University. An opportunity to devote his whole time and energy to research, and in particular to his early field of interest, elasticity, came in 1939 with the award of a Leverhulme Research Fellowship, with which he proceeded to Cambridge to work with Sir Geoffrey Taylor.

Sir Geoffrey soon recognized in him not only one of the few academic physicists interested in the mechanical properties of materials, but also one who was, in addition, gifted with a penetrating mind, experimental skill of a high order, and an infinite capacity for hard work. The association of the two men, started in 1939, persisted through the years; it produced, during the war period, a wealth of results, embodied in official reports, which were of the greatest value in the war effort, both in attack and in defence, and it was later to inspire much of the work of the research school which Davies established at Aberystwyth, whither he returned in 1945 and where he was appointed professor in 1946.

The research work at Aberystwyth was concerned with transient stresses and the propagation of stress waves in solids, and with detonation pressures and shock waves in gases. Much of this work arose from Davies's investigation, carried out in Cambridge and published in the *Transactions of the Royal Society* in 1948, of the Hopkinson pressure bar, originally devised in 1914 and largely neglected. The resurrection of the pressure bar as a modern instrument of research into transient high-pressure phenomena was typical of Davies's flair for rediscovering near-forgotten techniques; he had read deeply in the classical researches of the past, and nothing gave him more pleasure than to revive, from some forgotten paper by Kelvin or Rayleigh or Reynolds, some argument relevant to a modern problem.

The nature of this extensive research programme, of a type rare in British universities, inevitably brought to Aberystwyth many visitors from many lands, and to Davies himself many invitations to address conferences and symposia, and to join technical committees of various Ministries. In this way he very greatly enlarged his field of activity and became widely known as one of the leading authorities in his particular subject.

In 1956 he was invited to accept a visiting professorship at the California Institute of Technology at Pasadena. During seven months in the United States, he visited many American universities and research institutes and delivered numerous discourses; in quite characteristic fashion, he scorned American public transport, and drove his own car, acquired in New York on his arrival and disposed of there on his departure, across the American continent, over a total distance of 16,000 miles. Shortly after his return, Davies was again invited to visit the United States, to address the annual meeting of the American Institute of Mining and Metallurgical Engineers, held in New York in February this year; he had agreed to do so, and to visit other centres to renew contacts made during the previous year, but he died during the week of the meeting.

Research, though energetically and enthusiastically pursued, by no means represented the sum total of his activity. He was a teacher of unusual quality, and his lectures were invariably prepared with meticulous care and presented with superb lucidity. He was, in addition, a gifted administrator; his department was most efficiently organized, and he was, for a period, vice-principal of his College. He had also numerous other interests quite unconnected with his academic work. He was an accomplished musician with a particular interest in church music, and was organist and choirmaster in his own church at Aberystwyth and at the church which he attended at Cambridge; he had in his early years been an active cross-country runner and retained throughout a lively interest in all kinds of sport, his last hobby being yachting; and in his rare moments of relaxation, he was an avid reader of detective fiction.

In all the many facets of his life, he had an essential good-nature and personal charm which brought him a host of friends, varying immensely among themselves, but united by their regard for his warm humanity and patent sincerity. The key to his character undoubtedly lay in the fact that his roots remained firmly fixed in his native Welsh soil, and he carried into the wide world the virtues implanted in him by the devout, unhurried and unpretentious atmosphere of his upbringing. I. C. JONES

THE sad news of Prof. R. M. Davies's sudden death came as a shock to his many friends in the United States. He had been invited to lecture at the American Institute of Mining and Metallurgical Engineers Symposium on High-Speed Stressing of Solids in New York City on February 17. It was with great disappointment that we heard that, due to illness, it was necessary for him to cancel that visit.

He had been in the United States twice, once during the Second World War and again for the academic year 1956–57, when he was a visiting professor and lectured at the California Institute of Technology and at Rensselaer Polytechnic Institute. During this last visit, in addition, in his travel from coast to coast, he gave lectures at various universities and technical institutes.

Prof. Davies was a superb teacher, and all those who had the fortune to attend his lectures will never forget the excellence and brilliance of his presentation. As a result of his research, especially in the field of stress waves in solids, he leaves important and permanent contributions.

Those who knew R. M. Davies during the Second World War, when he was working under Sir Geoffrey Taylor at Cambridge for the Ministry of Supply, will always remember the very happy combination of 'G. I.' and 'R. M.'. His loss is particularly felt by the many who enjoyed his friendship and appreciated his warm personality, his deep Welsh sense of humour and the interest, helpfulness and understanding he always showed toward other people. These friends will realize that with the passing of R. M. Davies a very dear part of their lives has forever ended.

ENRICO VOLTERRA

Prof. T. Shimizu

TAYEI SHIMIZU, who died suddenly on January 30, was well known as the founder of the chief Japanese school of studies on steroids and especially bile acids. He was a pupil of the late Heinrich Wieland from 1920 until 1923, and again from 1929 until 1931, and from him returned to Japan with an enthusiasm in this field which proved lifelong.

Shimizu was born in Tokyo in 1889 and graduated from Kyoto University Medical School in 1915. He began his studies on bile acids there, under the late Prof. T. Araki. After his return from Germany in 1923, Shimizu was appointed professor of biochemistry at Okayama Medical School: he became president of this School in 1949 and, in 1952, president of Okayama University. He was elected a member of the Japan Academy in 1950, and in 1951 a member of the German Academy of Sciences.

Much of Shimizu's scientific contribution consisted in the persistence and skill with which he and his pupils followed up the observation of Hammarsten (1898), who found the steroid alcohol, scymnol, in the bile of sharks. This ought, perhaps, to have stimulated a much wider search for unusual bile salts, but it was not until Shimizu began his work that such a search was seriously undertaken. It was then pursued with remarkable zeal: for example, 4,000 toads were used to collect 5 litres of bile; from this were obtained interesting alcohols, finally carefully described by T. Kazuno (*Hoppe-Seylers Z.*, 266, 11; 1940) and the bile acids trihydroxysterocholenic and trihydroxy-*iso*sterocholenic, $C_{22}H_{46}O_5$, characterized by Shimizu and T. Oda (*Hoppe-Seylers Z.*, 227, 74; 1934), and by Shimizu and T. Kazuno (*Hoppe-Seylers Z.*, 239, 67; 1936). In later work, Y. Okasaki (*J. Biochem. Tokyo*, 36, 65, 77; 1944) collected 1·5 litres of bile from 100,200 specimens of a newt, *Diemyctylus phyrrhogaster*. An account of the work of Shimizu's school up to 1935 was included by him in a comprehensive book ("Über die Chemie und Physiologie der Gallensäuren", Muramato, Okayama, 1935), which he dedicated to Prof. Araki on his seventieth birthday. K. Ohta (*Hoppe-Seylers Z.*, 259, 53; 1939) reviewed the work at Okayama on fish bile, and later writers have summarized the Japanese contributions up to 1955 (for example, *Physiol. Rev.*, 35, 178; 1955).

The discoveries of Shimizu and his pupils have widened greatly the scope of chemical and physiological study of bile salts, and have stimulated a new awareness of the interest of biochemical species comparisons in this as in other fields.

In June 1957 Shimizu paid his last visit to Wieland, and also visited England for the first time for nearly forty years. He then, in spite of an indifferent command of English, read a paper on some of the work now being done by one of his former pupils, S. Hayakawa. He spent some time in the United States before returning to Japan.

Tayei Shimizu was a man of broad vision, good humour and modesty of character. His memory is held in affection by his friends and former pupils everywhere. G. A. D. HASLEWOOD

NEW FELLOWS OF THE ROYAL SOCIETY

At a meeting of the Royal Society on March 20, the following were elected to fellowships:

MICHAEL ABERCROMBIE, reader in embryology in the University of London at University College, distinguished for his researches in embryology, tissue culture, and wound healing.

DR. E. P. ABRAHAM, senior research officer at the Sir William Dunn School of Pathology, University of Oxford, distinguished for his work on the isolation and chemistry of antibacterial substances.

DR. J. R. BAKER, reader in cytology in the University of Oxford, distinguished for his researches on the chemistry of the cell.

PROF. J. A. BIRCH, professor of organic chemistry in the Victoria University of Manchester, distinguished for his studies on the structure and biogenesis of natural products.

PROF. SATYENDRANATH BOSE, vice-chancellor of the Visva-Bharati University, Santiniketan, India, distinguished as the discoverer of Bose-Einstein statistics.

DR. P. W. BRIAN, head of the Department of Microbiology, Akers Research Laboratories, Imperial Chemical Industries, Ltd., distinguished for his researches on microbiology and plant pathology.

EDITH BÜLBRING, demonstrator in pharmacology in the University of Oxford, distinguished for her work on smooth muscle and on the action of adrenaline.

DR. R. K. CALLOW, research chemist at the National Institute for Medical Research, London, distinguished for his work on steroid chemistry.

DR. F. DIXEY, director of Overseas Geological Surveys, London, distinguished for African geological researches, particularly in tectonics, geomorphology and ground-water hydrology.

PROF. P. P. EWALD, head of the Department of physics in the Polytechnic Institute of Brooklyn, distinguished for his outstanding contributions to the science of X-ray optics.

PROF. F. J. FENNER, professor of microbiology in the Australian National University, Canberra, distinguished for his work on microbiology, particularly the pathogenesis and epidemiology of mousepox and myxomatosis.

DR. W. H. GLANVILLE, director of the Road Research Laboratory, Department of Scientific and Industrial Research, Harmondsworth, distinguished for his researches on reinforced concrete and on road construction.

PROF. A. E. GREEN, professor of applied mathematics in the University of Durham (King's College, Newcastle upon Tyne), distinguished for important contributions to the mathematical theory of elasticity and hydrodynamics.

PROF. A. HADDOW, professor of experimental pathology in the University of London and director of the Chester Beatty Research Institute (Institute of Cancer Research, Royal Cancer Hospital), distinguished for his investigations into the chemotherapy of malignant disease.

DR. G. HIGMAN, reader in mathematics in the University of Oxford, distinguished for his contributions to the theory of groups.

PROF. A. ST. G. J. MCC. HUGGETT, professor of physiology in the University of London at St. Mary's Hospital Medical School, distinguished for his investigations on the physiology of reproduction and on the transfer of materials from mother to fœtus.

PROF. H. C. LONGUET-HIGGINS, John Humphrey Plummer professor of theoretical chemistry in the University of Cambridge, distinguished for his application of mathematics to problems in physical chemistry.

PROF. B. LYTHGOE, professor of organic chemistry in the University of Leeds, distinguished for his contributions to the chemistry of natural products.

PROF. S. K. MITRA, professor of physics and director of the Institute of Radio-Physics and Electronics, University of Calcutta, distinguished for his researches in many branches of upper atmosphere physics.

DR. C. H. MORTIMER, secretary of the Scottish Marine Biological Association and director of the Marine Laboratory, Millport, distinguished for his research upon lakes and lake-deposits, and the chemical and physical conditions which control life in them.

PROF. R. S. NYHOLM, professor of chemistry in the University of London at University College, distinguished for his contributions to inorganic chemistry, especially for his studies of complex compounds of the transition elements.

PROF. G. D. ROCHESTER, professor of physics in the University of Durham (Durham Colleges), distinguished for his researches on the cosmic radiation, and particularly for his contributions to knowledge of the unstable elementary particles.

PROF. O. A. SAUNDERS, dean of the City and Guilds College and head of the Department of Mechanical Engineering in the Imperial College of Science and Technology, University of London, distinguished for his contributions to the study of heat transfer and to the development of the internal combustion engine.

PROF. J. E. SMITH, professor of zoology in the University of London at Queen Mary College, distinguished for his researches on the principles of nervous organization as exemplified by lower animals.

DR. W. B. TURRILL, formerly keeper of the herbarium and library at the Royal Botanic Gardens, Kew, distinguished for his experimental and descriptive work on flowering plants of Britain and the Near East.

NEWS and VIEWS

Animal Physiology at Cambridge :

Dr. Ivan de Burgh Daly, F.R.S.

IVAN DE BURGH DALY, who is retiring from directorship of the Agricultural Research Council Institute of Animal Physiology, Babraham, studied medicine in Cambridge and at St. Bartholomew's Hospital and qualified as a physician in 1918 after serving in the R.N.A.S. He worked as a Beit Memorial Research Fellow at University College, London. He was professor of physiology in Birmingham (1927–32) and Edinburgh (1933–47), before going to Babraham as the first director of the Agricultural Research Council's Institute of Animal Physiology in 1948. In Starling's department he became interested in the physiology of the circulation and his skill as an engineer enabled him to construct elaborate apparatus for perfusing blood through isolated organs from dogs and recording the effects of drugs and of nervous stimulation on the distribution of blood and the resistance to flow. He is especially interested in the complex circulation in the lungs and is the leading authority on this subject.

During the past ten years he has been mainly responsible for the formation of the Institute at Babraham, with a distinguished staff of more than thirty scientists and ideal facilities for work on the physiology of larger animals than those normally studied in the physiological departments of medical schools. Under his leadership the Institute has grown rapidly and continues to grow. Scientists with wide experience in physiology, biochemistry and pathology have joined forces and are doing fundamental work on sheep, cows and pigs. His wisdom in resisting demands for the quick solution of problems of immediate practical importance is becoming more apparent as time goes by.

Prof. J. H. Gaddum, F.R.S.

JOHN HENRY GADDUM, who is to succeed Dr. I. de B. Daly as director of the Institute of Animal Physiology, qualified in medicine at Cambridge and University College Hospital. In 1925 he went to the Wellcome Physiological Research Laboratories at Beckenham, where he worked with the late Dr. J. W. Trevan, and left in 1927 to join Sir Henry Dale at the Medical Research Council Laboratories. At Hampstead he worked on the liberation of acetylcholine-like substances and established in collaboration with W. Feldberg that the nerve impulse in the superior cervical ganglion is transmitted by acetylcholine. He also developed methods for the bioassay of thyroid hormone and became interested in the interpretation of quantal bioassays ; this was a matter of some difficulty as the log dose–percentage mortality curve was sigmoid in shape. He introduced the idea of plotting the normal equivalent deviation against the logarithm of the dose used, thus obtaining a straight line. To avoid the use of a negative quantity it was later suggested that the normal equivalent deviation + 5 should be called the 'probit' and this probit figure should be plotted against the log dose. Gaddum's pioneer work in this subject was published in a Medical Research Council report in 1933. After occupying chairs at Cairo and University College, London, in 1942 he was appointed to the chair of materia medica in the University of Edinburgh in succession to the late Prof. A. J. Clark, where he has added great distinction to the Department during the past sixteen years.

Gaddum has been interested in a wide field of pharmacological experiment, particularly in respect of the pharmacologically active substances obtained from tissue extracts. He has done a great deal to elucidate the substances liberated when autonomic nerves are stimulated. This work started with acetylcholine and noradrenaline, and he has continued it with 5-hydroxytryptamine and substance *P*. He has been interested in the antagonism of 5-hydroxytryptamine by lysergic acid diethylamide, and recently he has edited a monograph on polypeptides which stimulate plain muscle. He has been responsible for the statistical analysis of many bioassay procedures, and has written the appendix to "The British Pharmacopœia" on the mathematical basis of bioassay ; he has also written a very popular text-book of pharmacology, now in its fourth edition. He has been a member of the Committee of the Medical Research Council from 1948–51 and a Fellow of the Royal Society since 1945. His appointment as director of the Agricultural Research Council's laboratories at Cambridge will give a great stimulus to the study of pharmacology in connexion with agricultural problems.

Materia Medica at Edinburgh : Dr. W. L. M. Perry

THE appointment is announced of Dr. W. L. M. Perry to the chair of materia medica in the University of Edinburgh in succession to Prof. J. H. Gaddum, who is leaving Edinburgh to become director of the Agricultural Research Council Institute of Animal Physiology at Babraham. Dr. Perry, who graduated in medicine at St. Andrews in 1943, joined the scientific staff of the Medical Research Council at the National Institute for Medical Research in 1947, having completed a tour of duty in the Colonial Medical Service in West Africa. In his first research, Dr. Perry collaborated with Dr. F. Hawking in work which revealed the indirect mode of chemotherapeutic action of proguanil. Thereafter, he turned to subjects on the borderline between physiology and pharmacology, publishing a number of papers on transmission in the autonomic nervous system, and at the same time developing an interest in the principles and technique of biological assay, to which subject he made notable contributions. In 1951, Dr. Perry was appointed director of the Division of Biological Standards at the National Institute for Medical Research ; in this position he has carried with apparent ease a burden of work and responsibility which, especially during the past two years, has been unexpectedly heavy because of the involvement of the Division in the safety testing of poliomyelitis vaccine. Dr. Perry thus goes to Edinburgh having behind him an unusual breadth of scientific and administrative experience ; with the return to laboratory research that his new post will permit, it can be confidently anticipated that he will not only uphold but also add to the distinguished traditions of the chair of materia medica in Edinburgh.

Viking Fund Medals for 1957

THE 1957 Viking Fund Medals and prizes of 1,000 dollars each for outstanding contributions to anthropology have been awarded to Drs. Raymond A. Dart, James B. Griffin and Margaret Mead. Dr. Dart was elected by the American Association of Physical Anthropologists as medallist in physical anthropology. He is dean of the Faculty of Medicine at the University of the Witwatersrand. Since 1925, Dr. Dart has discovered many specimens of a sub-human creature, *Australopithecus prometheus*. He postulated that this proto-man belonged to the hominid rather than the ape family, and that Africa, not Asia, was the birthplace of man. In 1955, Dr. Dart discovered *Australopithecus* buried with crudely-worked tools of a Pebble Culture. Dart's theory was thereby accredited and his find recognized as the most primitive creature known to date that can be called human. Dr. Griffin, director of the Museum of Anthropology and professor of anthropology at the University of Michigan, was cited by the Society for American Archæology for his great influence in promoting the aims of scientific archæology, and for his unsurpassed knowledge of the form, range and distribution of artefact styles in North America. Dr. Mead was selected as the 1957 medallist in general anthropology by the American Anthropological Association. She is associate curator of ethnology at the American Museum of Natural History, and has done more than any other single individual to introduce anthropology to the American public. A prolific writer, among Dr. Mead's most popular books are "Coming of Age in Samoa", "Growing Up in New Guinea", "Male and Female" and "New Lives for Old".

The Viking Fund Medals and awards originated upon the suggestion of Dr. Axel L. Wenner-Gren, the Swedish industrialist who endowed the Foundation now bearing his name. Since 1946, the Wenner-Gren Foundation has provided the medals and prizes of 1,000 dollars, which are awarded to the general anthropologist, archæologist and physical anthropologist who has made a significant contribution to his field.

Train Control on Railways in Britain

In replying to a debate on automatic train control on March 7, on an adjournment motion moved by Mr. P. C. Goodhart, Mr. G. R. H. Nugent, Parliamentary Secretary to the Ministry of Transport and Civil Aviation, said that in the past 46 years, 698 formal inquiries had been made in Britain into rail accidents in which 1,599 people were killed. Of these accidents, automatic train control could probably have avoided 11 per cent and 31 per cent of the fatalities. Track circuiting is a further safety device which serves primarily to record that a train is in a particular sector of the track, and with colour light signals, which are easier to see, especially at night and in fog, and can be linked with automatic train control and track circuits and the control board in the signal box, could make a big contribution to traffic safety but without eliminating the human element. Automatic train control was started on the initiative of the Great Western Railway in 1905, but the equipment of the main lines of Britain was not completed until 1930, and the non-contact magnetic Hudd system evolved in the 1930's and tried on the London, Midland and Scottish Railway was not finally approved by the Minister of Transport until 1947. In 1948, the British Transport Commission decided to make a wide extension of automatic train control, colour light signals and track circuits: the Great Western system was regarded as unsuitable for electric lines and its heavy mechanized parts were unsuitable for permanent and universal adoption. The Commission is also convinced that a non-contact magnetic system superior to the Hudd system could be found; but although full-scale trials have been carried out since 1950 on the east coast line, as was expected, many difficulties were encountered. The routes carrying the greatest train frequency and speed would receive the earliest attention, and installation is in no way retarded by capital restrictions.

Millenary Celebrations of Al-Mas'udi

The millenary of Al-Mas'udi, the tenth century Arab geographer, traveller and encyclopædist, was recently celebrated at the Muslim University, Aligarh, under the joint auspices of the Institute of Islamic Studies, Aligarh, and the Indian Society for the History of Science. About thirty papers were received from all parts of the world, including Britain, Egypt, France, Holland, India, Iran, Lebanon and the United States

Mr. A. A. A. Fyzee, vice-chancellor of the University of Jammu and Kashmir, devoted his presidential address to the need for studies of the humanities in the university, particularly in view of the technological changes in progress in India. He stressed that the aim was not to produce theologians, which has been the dominant tendency in the past, "but to produce men of understanding and intelligence, of balanced judgment and critical appreciation of the past". Prof. M. S. Thacker emphasized the collaboration that had existed between the Arab countries and India in the search for knowledge. After giving a general survey of Al-Mas'udi's contribution in the field of science, he suggested the great need for a scientific study of the available material, particularly from the point of technology and its relation with the intellectual attainments of the age. Prof. N. Ziadeh discussed the geographical, climatological and certain social details of Sham (Syria) given by Al-Mas'udi, and Dr. M. Shafi dealt with his geographical contributions, particularly in the field of human geography, which Al-Mas'udi did much to establish on scientific lines. In a general survey of science at the time of Al-Mas'udi, Mr. A. Rahman emphasized its characteristic features, namely, its association with the concept of God as the driving force of the universe, and its relation to the Greek philosophical outlook. It is proposed that the contributions shall be published in the form of a commemorative volume.

Society for Visiting Scientists

The report of the secretaries on behalf of the Council of the Society for Visiting Scientists to the tenth general meeting on December 19 records continued restriction, for financial reasons, of the Society's activities, although the Overseas Science Students' Association continues to flourish. The Society has now nearly 2,900 members, from sixty-five countries, but only one reception could be held during the year, for participants in the symposium of the Royal Astronomical Society and the Royal Meteorological Society on "Planetary Atmospheres and Convection in Rotating Fluids". The Society's information service is constantly growing, helped by generous gifts of periodicals and reference books, but only limited success attended an attempt to increase the income from industry. Five most successful discussion meetings were held during the year, dealing respectively with "The Effects of Low Temperatures on Mammals and their Tissues"; "The Widening Field of Application of Electronic Computers"; "Taste and Smell"; "Water Quality Problems in the United Kingdom"; and "Science and Furniture". The lively discussion which characterized all the Society's meetings is further indication of the value of its work and of the desirability that adequate financial support should enable it to make its full contribution in assisting scientific co-operation and understanding.

The Parapsychological Association

The formation of the Parapsychological Association, an international professional group of research workers in the field of extrasensory perception and psychokinesis, has been announced. The objects of the Association are to advance parapsychology as a science, to disseminate knowledge of the field, and to integrate the findings with those of other branches of science. Full membership is restricted to those with doctorate degree training or equivalent. The founding officers are: *President,* R. A. McConnell (Biophysics Department, University of Pittsburgh); *Vice-President,* G. R. Schmeidler (Psychology Department, City College of New York); *Secretary,* R. White (Parapsychology Laboratory, Duke University); *Treasurer,* R. J. Cadoret (Duke University); *Members of Council,* M. Anderson (Duke University), K. Osis (Parapsychology Foundation of New York) and W. G. Roll (University of Oxford).

Conference on High Energy Nuclear Physics

More than 200 scientists from twenty-six nations have been invited to participate in the 1958 Annual International Conference on High Energy Physics, organized by the European Organization for Nuclear Research (CERN), in Geneva during June 30–July 5. Participation at the 1958 Conference is by invitation only. Among the 226 scientists invited so far, more than a hundred have already accepted, among them: Prof. W. Heisenberg, of Germany; Prof. Leprince-Ringuet, of France; Prof. E. Amaldi, of Italy; Prof. Hideki Yukawa, of Japan; Prof. P. Scherrer and Prof. W. Pauli, of Switzerland; Sir John Cockcroft and Prof. P. M. S. Blackett, of the United Kingdom; and from the United States, Dr. C. N. Yang, Dr. T. D. Lee, Dr. J. R. Oppenheimer and Prof. L. W. Alvarez. During ten plenary sessions in the auditorium of the Physics Institute of the University of Geneva, papers will be presented on nucleon structure; the nucleon and its interactions with pions, photons, nucleons and anti-nucleons; fundamental theoretical ideas; strange particle production and interaction; invariance principles and selection rules, and weak interactions. The conference proceedings, including original papers presented, will be published by CERN.

Second Geneva Conference on Peaceful Uses of Atomic Energy

The second International Conference on the Peaceful Uses of Atomic Energy is to be held in Geneva during September 1–13, under the auspices of the United Nations (*Nature,* 180, 217; 1957). The president of the Conference is to be Prof. F. Perrin, of the Commissariat à l'Energie Atomique de France, and the secretary-general, Dr. S. Eklund, of Sweden. Two atomic energy exhibitions will be held in Geneva during the Conference. The first will be a scientific exhibition under the auspices of the United Nations, at the Palais des Nations. A United Kingdom exhibit, 5,000 sq. ft. in extent, is being arranged by the U.K. Atomic Energy Authority, to include a model of the thermonuclear research apparatus, ZETA. The other exhibition, which will be commercial, is the International Exhibition on the Peaceful Uses of Atomic Energy, at the Palais des Expositions. The British section is being organized by the Nuclear Energy Trade Associations' Conference, which represents all major British firms concerned with atomic energy. People interested in attending the Conference as observers should apply for passes not later than April 19. Representatives from industrial firms who are working in the atomic energy field should apply to Mr. M. H. L. Whitehouse, Nuclear Energy Trade Associations' Conference, 32 Victoria Street, London, S.W.1, and all others to Mr. J. C. Walker, United Kingdom Atomic Energy Authority, 11 Charles II Street, London, S.W.1. The United Kingdom representatives on the United Nations scientific secretariat for the Conference will be Mr. F. Hudswell and Mr. W. B. Woollen (Atomic Energy Research Establishment, Harwell) and Mr. T. E. F. Carr (Medical Research Council).

Isotope Courses at Harwell

A course on radioisotopes, designed to give senior executives in industry an appreciation of the possible applications of those materials, will be held at the Harwell Isotope School during September 23–26. Two similar courses have been arranged for April 15–18 and July 8–11 for members of the Institute of Directors only. The course consists of lectures on the elementary principles of work with radioactive isotopes with the emphasis on their application as tools in industry and research. The lectures will be given in as non-technical a manner as possible by scientists experienced in the field; they will be supplemented by visits to a reactor and to the laboratories of the Isotope Division at Harwell and at the Wantage Radiation Laboratory near Harwell. The lectures and demonstrations will be given in the Cockcroft Hall at Harwell. Further information can be obtained from the Registrar, Isotope School, Atomic Energy Research Establishment, Harwell.

City and Guilds of London Institute: Fellowships

The Council of the City and Guilds of London Institute have conferred the Fellowship of the Institute (F.C.G.I.) upon the following past students of the City and Guilds College or Finsbury Technical College in recognition of their distinguished contributions to industry or the professions in which they are engaged: D. H. Alexander, principal, College of Technology, Belfast; W. A. Coates, retired, former director of Metropolitan-Vickers Electrical Co., Ltd.; G. H. Hopewell, managing director, Foster Wheeler, Ltd.; F. C. Wright, managing director, Standard Telephones and Cables, Ltd.

The Night Sky in April

Full moon occurs on April 4d. 03h. 45m. U.T., and new moon on April 10d. 03h. 23m. The following conjunctions with the Moon take place: April 5d. 04h., Jupiter 2° N.; April 9d. 02h., Saturn 3° S.; April 13d. 13h., Mars 7° S.; April 15d. 00h., Venus 4° S. There will be an annular eclipse of the Sun on April 19, invisible at Greenwich. Mercury is favourably placed for observation during the first week of the month, setting at 20h. 20m. on April 1; its stellar magnitude on that date is + 0·5. Later in the month, Mercury is too close to the Sun for observation. Venus is a morning star, visible low in the south-east before sunrise. It rises at 4h. 10m., 3h. 50m. and 3h. 25m. on April 1, 15 and 30, respectively; its stellar magnitude is about − 4·0. During the month its distance from the Earth increases from 58 to 80 million miles and the visible portion of the apparent disk from 0·450 to 0·600. Mars rises at 4h. 00m., 3h. 30m. and 2h. 50m. at the beginning, middle and end of the month, respectively. It is visible low in the south-east before sunrise, but conditions are not very favourable; its stellar magnitude is + 1·0. Jupiter rises at 20h. 05m., 19h. 00m. and 17h. 45m. on April 1, 15 and 30, respectively, and sets at 4h. 20m. on April 30; it is visible throughout the night. Opposition is on April 17; the planet is near Spica. The stellar magnitude of Jupiter is − 2·0, its distance from the Earth on April 15 being 410 million miles. Saturn rises at 1h. 05m., 0h. 10m. and 23h. 10m. at the beginning, middle and end of the month, respectively; it is east of θ Ophiuchi. Its stellar magnitude is + 0·6 and it is at a distance of 890 million miles from the Earth on April 15. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: April 6d. 04h. 20·5m., α Lib. (*D*); April 25d. 20h. 34·9m., 68 Gem. (*D*). *D* refers to disappearance. The Lyrid meteors are active during April 20–22. Conditions are very favourable; the radiant is near right ascension 18h. 04m., declination + 33°.

Announcements

THE Council of the Royal Microscopical Society has made the following elections to honorary fellowship of the Society: Dr. Edwin H. Land, president of the Polaroid Corporation, Cambridge, Massachusetts, in recognition of his contributions to microscopy; Dr. Maria Rooseboom, curator, National Museum for the History of Science, Leyden, in recognition of her valuable work in connexion with the history of microscopy.

THE Council of the Iron and Steel Institute has announced the following awards for 1958: Bessemer Gold Medal for 1958, to Mr. W. F. Cartwright (Steel Company of Wales, Ltd.); Sir Robert Hadfield Medal for 1958, to Mr. W. C. F. Hessenberg (British Iron and Steel Research Association); Ablett Prizes for 1957, £50 each to Mr. C. E. H. Morris and Mr. R. N. Dale (Steel Company of Wales, Ltd.), for their paper, "Planning the Conversion of a High-lift Slabbing Mill to a Universal Mill" (*J. Iron and Steel Inst.*, April 1957).

DR. B. R. NIJHAWAN, director of the National Metallurgical Laboratory, Jamshedpur, has been given the award of 'Padma Shri' by the President of the Republic of India, in recognition of his exceptionally distinguished services in the field of science in India.

MR. J. D. HANDYSIDE has been appointed controller of research, National Institute of Industrial Psychology, with effect from April 1.

THE Institution of British Agricultural Engineers is able to offer, through the generosity of Shell Mex and B.P., Ltd., a number of bursaries for award to candidates eligible for entry to the final-year course of study leading to the examination in July 1959 for the National Diploma in Agricultural Engineering. These bursaries are normally available in units of £50, but their disbursement may be varied at the discretion of the Examination Board. The conditions governing the award may be obtained from the Secretary of the Institution of British Agricultural Engineers, 6 Buckingham Gate, London, S.W.1. The closing date for receiving completed applications is May 1, 1958.

THE Physical Society is holding a conference on "Nuclear Physics" at the Cavendish Laboratory, Cambridge, on April 10–11. Further information can be obtained from the Secretary, The Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

THE 1958 National Symposium of the U.S. Institute of Radio Engineers Professional Group on "Microwave Theory and Techniques" will be held at Stanford University, Stanford, California, during May 5–7. Further information can be obtained from Glenn H. Keitel, Publicity Chairman, 1958 PGMTT National Symposium, 601 California Avenue, Palo Alto, California.

THE 1958 International Conference on Semiconductors, sponsored by the International Union of Pure and Applied Physics, will be held at the University of Rochester, New York, during August 18–22. Further information can be obtained from M. H. Hebb, P.O. Box 1088, Schenectady, New York. Abstracts must be received by May 1.

A ONE-DAY conference on statistical sampling in industry, organized by the Birmingham Group of the Industrial Applications Section of the Royal Statistical Society, will be held at the Birmingham College of Technology on May 7. Further information can be obtained from D. Goldberg, Lamp and Lighting Co., Ltd., Melton Road, Leicester.

AN informal discussion on "The Structure and Physical Chemistry of Nucleic Acids and Nucleoproteins" will be held in the Department of Chemistry, University of Birmingham, on September 17–18, under the auspices of the Colloid and Biophysics Committee of the Faraday Society. Papers on the following topics will be read: nucleic acids (especially ribonucleic acid), synthetic polynucleotides, nucleoproteins. Members of the Faraday Society and others who wish to take part should notify Dr. A. R. Peacocke, Department of Microbiology, University of Birmingham, Edgbaston, Birmingham 15, to whom titles of papers should be sent before June 1.

THE essay subjects for this year's *Endeavour* Prizes of the British Association for the Advancement of Science will be as follows: education for an age of science; rockets and satellites and their scientific significance; photography and cinematography in science; chemicals from petroleum; Darwinism to-day; the measurement of time. The essays must be sent in by June 1 and should not exceed four thousand words. Competitors must be less than twenty-five years old, and the prizes will be 50, 25 and 15 guineas, with two special awards of 5 guineas to those less than eighteen. Further information can be obtained from the Assistant Secretary, British Association for the Advancement of Science, Burlington House, Piccadilly, London, W.1.

ERRATA. Referring to the article entitled "Non-Conservation of Parity" in *Nature* of February 15, Prof. A. Salam writes: "p. 448 (1*d*), column 2, line 5, for 'right' read 'left'; (*e*) for subscript '*L*' read '*R*'. I am grateful to Dr. J. R. Holt for pointing out these errors".

RECENT ADVANCES IN NUCLEAR PHYSICS

A NEW series of meetings has been inaugurated at the Royal Society at which normally three Fellows will be invited to present statements on topics of current interest. Unlike the usual meetings for the reading of papers and the discussion meetings which are held periodically, the proceedings at these new meetings will not be published and the speakers will be free to treat the subject in a broader and perhaps more speculative manner than would be the case if their words were to be printed in the Society's *Proceedings* and *Transactions*.

The subject of the first meeting, held on February 20, was "Recent Advances in Nuclear Physics". Each of the three speakers, Profs. D. H. Wilkinson, W. E. Burcham and R. E. Peierls, spoke for half an hour. They chose to discuss aspects of what is probably the most significant advance made in the past twelve years, namely, the discovery that the motions of nucleons inside a nucleus are not strongly correlated but are largely independent of each other. In nuclear structure studies discussed by Prof. Wilkinson, this phenomenon has led to the establishment of the 'nuclear shell-model', in which, as a first approximation, nucleons in a nucleus move in an overall common potential V. The counterpart of the shell-model in nuclear reaction studies is the 'optical model' described by Prof. Burcham.

Prof. Wilkinson spoke specifically on "The Structure of Light Nuclei", using the shell-model to interpret the considerable body of data that has accumulated on nuclear-level schemes, transition probabilities, and magnetic moments. In applying the model, one introduces two types of forces acting on the nucleons over and above the common potential V. The first type of force is that acting between pairs of nucleons. By direct analogy with Coulomb forces acting between pairs of electrons in an atom, these forces tend to couple the orbits of the nucleons together to produce L–S coupling. The second type is that which couples the spin of each nucleon to its orbit (like the Thomas force in the atom) and tends to produce j–j coupling. In the presence of both types of forces, the coupling situation in a nucleus is described as intermediate and is characterized by the ratio of the effective strength of the inter-nucleon forces to the spin-orbit forces. This ratio is the most significant parameter available when attempting to fit observations.

Prof. Wilkinson showed an extensive series of slides representing the work of many people and containing comparisons of experimental data on various light nuclei with the predictions of the shell-model. The agreement is impressive, especially in such cases as carbon-13 and nitrogen-13, where the observed values of five different kinds of data are fitted with the same value of the parameter. A satisfactory feature of the fits is that the 'best values' of the effective strengths of the two types of forces vary smoothly with mass numbers and are in reasonable agreement with theoretical predictions.

Prof. Burcham discussed "The Optical Model and Nuclear Reactions". The optical model attempts to incorporate features of both the 'compound nucleus' model of nuclear reactions, and the shell-model of nuclear structure. Corresponding to the latter model, the effects of a nucleus on the motion of a bombarding nucleon can be represented by a real potential V, which merely deflects it. Compound nucleus formation, which occurs as a result of a collision in which the incident nucleon loses energy to a target nucleon, may be included by adding to V an imaginary iW. In the manner well known in optics, such a term represents absorption. Small values of W correspond to small absorption, that is, there is little probability of formation of compound nuclei; large values correspond to large absorption and large probability of formation of compound nuclei; moderate values correspond to intermediate situations in which the number of nucleons passing through the nucleus compares with the number that are absorbed into the compound nucleus. For any given values of V and W, one may calculate the absorption, shape-elastic and total cross-sections, and if a spin-orbit potential is included, the polarization of elastically scattered nucleons. Comparison with observation then enables the potentials to be determined.

At low energies (less than 5 MeV.) total cross-sections for neutrons exhibit variations with energy. Peaks occur at energies corresponding to single-particle resonances in the real potential V, and the fact that such peaks are observed at all means that W must be rather small (about 2 MeV., which is much less than the value of V, ~ 40 MeV.).

Observations at higher energies up to 1,000 MeV. suggest that W increases with energy up to 100 MeV., then flattens off and increases again at energies greater than 400 MeV., where absorption due to meson production is important. In contrast, V appears to decrease steadily until it becomes zero near 350 MeV. (This may be shown directly by use of the optical theorem stating that the total cross-section is equal, apart from known constant factors, to the imaginary part of the forward-scattering amplitude. The observed values of the total and forward scattering cross-sections at 350 MeV. show that the real part, which is proportional to V, must be very small.)

The optical model has proved to be very useful for the analysis of nuclear cross-sections, just as the shell-model is useful for interpreting data on nuclear structure. For many years, it was argued that the type of nucleon motion envisaged by the shell-model is in such contrast to the strong short-range nuclear forces that the model could not possibly be valid. Acceptance of the model has come only with its convincing success in applications. Now that the applicability of the shell and optical models in practice is so well confirmed, much attention has been given to the theoretical problem of understanding why the models work. Prof. Peierls devoted his talk, "The Theoretical Basis of the Shell-Model and Optical Model", to this matter.

It appears that the basic reason why nuclear forces are not nearly as effective in nuclear matter as one might guess is the action of the Pauli Principle. A system of Fermi particles with no interactions in its lowest state has one particle in each of the single-particle momentum states up to the Fermi level. When interactions are introduced, even though they may be strong and of short range, they will not seriously modify the state, since all collisions with small momentum transfers are forbidden. Unfortunately, such an approach, using interactions containing sufficient exchange forces to produce saturation, gives too little binding-energy. The source of this discrepancy appears to be the fact that nuclear saturation arises only partly from exchange forces, another cause being the infinitely repulsive core in the nuclear interaction. The presence of this core means that shell-model wave-functions cannot possibly be correct when any two nucleons are separated by just the range of the core. Nevertheless, since the range of the core is considerably smaller than the mean inter-nucleon spacing, they are expected to be correct otherwise. Mathematical techniques have been developed for taking account of the effects of the cores in the wave-functions, and it is believed that one has, in principle, a reliable scheme for computing nuclear properties, especially binding-energies, using realistic nuclear forces. The main trouble, in practice, is the great labour involved in calculation. This reduces to reasonable magnitude only when considering large hypothetical systems in which surface effects are negligible. An important by-product of such calculations is the estimation of the nuclear potential, V, as a function of the momentum of a nucleon. This emerges in an iteration procedure in which one assumes values for V, then calculates new values and continues until convergence is obtained. It can be identified with the real part of the potential of the optical model, and so the calculations predict this quantity as well as the nuclear binding energies.

The meeting ended after the speakers answered a few questions from the audience. A. M. Lane

BIOCHEMISTRY OF GLUTATHIONE

The Biochemical Society arranged a symposium on glutathione, organized by Dr. E. M. Crook and held on February 15 at the Senate House, University of London. As indicated by Prof. R. H. S. Thompson's opening remarks, the subject is attractive in bringing together a wide range of disciplines: purely chemical and analytical studies, plant and animal biochemistry, and pharmacology, toxicology and general biology.

The metabolism of glutathione in plants is notable, as described by Dr. L. W. Mapson (Low Temperature Research Station, Cambridge), for the well-defined systems which catalyse both oxidation and reduction at its sulphide group. Glutathione reductase has been found in most organisms in which it has been sought. More characteristic of plants than animals is dehydroascorbic acid reductase, which catalyses the interaction of reduced glutathione with the oxidized form of ascorbic acid. The reduced ascorbic acid formed can be oxidized by established routes, and about a quarter or a half the oxygen uptake of preparations of germinating pea cotyledons may proceed by this route, providing an example of the respiratory function envisaged for glutathione by Hopkins and others. However, attempts to demonstrate the generation of high-energy bonds during these changes have so far been unsuccessful.

Glutathione in Animal Tissues

In animal tissues there appears relatively little scope for this route of oxidation; but oxidation by purely chemical routes, for example, by exchange with other disulphides, can readily occur. This and other aspects of the chemistry of glutathione were surveyed by Dr. F. A. Isherwood (Low Temperature Research Station, Cambridge); thus transacylation also occurs spontaneously between the thiol group of glutathione and S-acyl compounds. Oxidation and mercaptide formation at the glutathione thiol group form the basis of two analytical methods for glutathione described in detail by Dr. C. G. Thomson (Institute of Psychiatry, London), who compared results with these methods with those obtained using glyoxalase. A considerable measure of agreement was found when these techniques were applied to blood and to cerebral tissues. Each tissue, however, presents its own problems in fixation, extraction, and the presence of substances likely to interfere in assay, as was evident also from discussion.

Reviewing glutathione in animal tissues generally, Dr. P. C. Jocelyn (University of Edinburgh) described recent studies of its synthesis. Synthesis proceeds through γ-glutamylcysteine and is catalysed by two distinct synthetases in tissues including erythrocytes and liver. In the liver, the synthesis appears to be affected by growth hormone and adrenaline; the extent to which vitamin B_{12} is involved in the maintenance was also appraised. Although glutathione has been suggested as a substrate in the further synthesis of proteins, experiments on incorporation of amino-acids into ovalbumin, and other lines of evidence, have failed to support the idea.

In neural tissues, Prof. H. McIlwain (Institute of Psychiatry, University of London) described the determination of glutathione in the brain fixed rapidly *in situ*, and its maintenance during *in vitro* experiments. Assimilation, synthesis, and breakdown of glutathione in cerebral tissues proceed at relatively slow rates, as also does its acylation. Deacylation is more rapid, especially of an acetylglycyl glutathione. Enzyme catalysis of the oxidation of glutathione has not been found, but the tissue possesses a very active glutathione reductase which forms the main route of oxidation of reduced triphosphopyridine nucleotide. This system operates at nearly maximal rate at the low concentrations of oxidized glutathione and of reduced triphosphopyridine nucleotide which are native to the tissue. Indeed, its operation would appear to be the main factor in securing the great preponderance of the reduced form of glutathione normally found *in vivo*, and to be necessary if glutathione is to perform the role so often ascribed to it, of maintaining thiol enzymes and coenzymes in their active, reduced, forms. Participation of glutathione in cerebral carbohydrate metabolism is well established, and change in level of blood glutathione has been reported to be associated with mental disease. Administration of large quantities of glutathione to man with the intention of altering mental status has displayed the relatively small central effects produced in this way, in distinction to the marked effects of other thiols on the nervous system. Blood constituents are, however, altered by the administration of such quantities.

Analogues of glutathione have been found to occur naturally in the lens of the eye. Their isolation was described by Dr. S. G. Waley (Nuffield Laboratory of Ophthalmology, Oxford); they differ from glutathione at its cysteinyl residue, ophthalmic acid being γ-glutamyl-α-amino-*n*-butyrylglycine, and norophthalmic acid the alanyl derivative. They appear to be produced in the lens by the system which synthesizes glutathione, for competition can occur when substrates for more than one product are provided. Glutathione synthesis is affected also by the X-irradiation which induces cataract; after exposure, the glutathione concentration in the lens falls, but causal relationship between this change and the cataract is still under investigation. A further intriguing product isolated from the lens is S-sulphoglutathione, which can be formed from sulphite and oxidized glutathione.

Radiation Damage; Glyoxalase

In reviewing relationships between thiols and radiation damage generally, Dr. D. B. Hope (M.R.C. Radiobiological Research Unit, Harwell) described the inactivation of thiol enzymes brought about *in vitro* by irradiation. This has not been observed *in vivo*, so the enzymes involved are in some way protected, and attempts have been made to enhance the normal protection by administered substances. Glutathione to a small extent protects mice from the lethal effects of X-irradiation, but cysteamine, dithiocarbamates, and other compounds are more effective; they have in common the property of lowering the body temperature of animals.

Interesting points regarding glyoxalase came from several contributors. This is the system converting methylglyoxal to lactic acid, in which coenzyme status for glutathione was first established, and which once appeared to constitute the main route of glycolysis in many organisms. Its displacement from this role was exemplified in cerebral tissues: lactic acid formation from methylglyoxal, though rapid, is inadequate to account for the high rates at which lactic acid was afterwards found to be produced from glucose. That the glyoxalase system comprises two enzymes, adumbrated by F. G. Hopkins in his posthumous paper with E. J. Morgan, is generally agreed. Perhaps surprisingly, the immediate substrate for glyoxalase I is still debated, Dr. Waley's evidence favouring the hemimercaptal between glutathione and methylglyoxal. In this system in the lens, ophthalmic acid acts as a competitive inhibitor. Glyoxalase I yields S-lactoylglutathione, the substrate of glyoxalase II. However, a preparation from cerebral tissues is reported to hydrolyse at least one other substrate more rapidly than glyoxalase intermediate: this is S-acetylglycylglutathione. Hydrolytic enzymes have also been found in mouse liver which are specific to S-acyl derivatives of glutathione.

Concluding remarks by Dr. C. P. Stewart (University of Edinburgh) emphasized these and other aspects of the biochemistry of glutathione in which further investigation is still required. He indicated how studies of radiation damage, and the *S*-sulphoglutathione from the lens, offer hints on compounds intermediate in the conversion of —SH to —S.S— glutathione, a process likely to involve two stages.

NATIONAL OCEANOGRAPHIC COUNCIL

ANNUAL REPORT 1956–57

THE report of the National Oceanographic Council for 1956–57 (pp. v+34. Cambridge: At the University Press, 1957. 5*s*. net) describes the work carried out by the National Institute of Oceanography during the year ending March 31, 1957. The activities cover the two main fields of marine physics and marine biology, and follow the broad objectives set in previous years.

In marine physics, the technique of determining deep currents by tracking a neutrally buoyant float, drifting freely at a predetermined depth, has been exploited further. The most significant piece of work was the discovery of a southerly-flowing deep current, at depths greater than 2,500 m., beneath the Gulf Stream. This was achieved in the course of a joint expedition by R.R.S. *Discovery II*, and the U.S. research vessel *Atlantis* to an area about 150 miles off the coast of South Carolina. Other measurements of deep currents were made during the year in the Faeroe-Shetland Channel, off the Sogne Fjord, and in a region north of Madeira.

Waves and swell have been one of the Institute's main interests since its inception, and during the past year or two increasing attention has been given to their effects on the rolling, pitching and heaving of ships. The work on this subject has attracted much interest among scientists and engineers concerned with ship motion, in Great Britain and in the United States. A series of theoretical papers has also been published, treating the statistical properties of waves as those of a random, moving surface. Other studies of waves include their relation to microseisms and the relation of both to the movements of storms generating them. Turning to waves on a longer time-scale, basic research with a bearing on storm surges has been continued, both by mathematical models and by electrical analogue techniques.

The productivity of oceanic waters is one of the Institute's major objectives in marine biology, and advances have been made in instrumental and operational techniques for this purpose. An example of this is provided by work on the quantitative sampling of zooplankton from water layers at various depths. Research at sea on organic productivity included three weeks observations in one position, 600 miles west of Portugal, during the autumn of 1956. Repeated measurements were made from *Discovery II* of the light energy, rate of photosynthesis and the standing crop of phytoplankton and zooplankton.

Another broad field of investigation concerns the oceanic distribution of marine organisms. Comprehensive studies have been made of the distribution of various species of the plankton fauna in the Southern Ocean and in the Benguela Current. An interesting feature is the tendency for populations of different species of zooplankton to be segregated in concentric circumpolar zones. A technique for obtaining underwater photographs of squid has been developed and used successfully at depths of 300–1,000 m.

Work has been continued on the distribution and life cycles of whales, a knowledge of which is required in formulating international regulations. An investigation is being made of two alternative methods of age determination in baleen whales: by the laminations in the ear plugs and from the accumulated corpora albicantia in the ovaries. A comprehensive paper has been published on the biology of sperm whales, and a study of ambergris is in progress. Work is also being done on the geographical distribution of the various species of whale and their movements between one ocean area and another.

R.R.S. *Discovery II* was kept in full commission throughout the year, although for three months she was on hire to the Admiralty and so not employed on the Institute's research programme. For six weeks in July–August 1956 the ship was lent to the Department of Geodesy and Geophysics of the University of Cambridge, for a cruise to the Mid-Atlantic Ridge, which included seismic studies and measurements of heat flow through the sea bed.

The Institute has continued to be directed by Dr. G. E. R. Deacon with Dr. N. A. Mackintosh as deputy director. Its total staff is about eighty (excluding the officers and crew of *Discovery II*), of whom thirty-six are in the scientific and experimental officer grades. In addition, seven visiting scientists from overseas were working in the Institute during the year. The expenditure on the year's work amounted to £193,000, of which £78,000 was for running *Discovery II*. The main source of income was £110,000 in grants from the United Kingdom Government. Commonwealth Governments contributed £9,000. The Treasury has decided to increase its grants to £175,000 per annum for the next five years and this should go a long way towards ensuring the further development of the Institute's research programme.

K. F. BOWDEN

OPENCAST MINING

THE Opencast Coal Bill, which had an unopposed second reading in the House of Commons on January 22, is a complicated Bill which replaces the powers at present exercised under Defence Regulations by a system of planning control, acquisition and compensation incorporating some of the main points made in the Franks report. It provides that no opencast operations can take place without the permission of the Minister, who will, in his consent, insert conditions ensuring that damage is reduced to the minimum, and, when agricultural land is affected, that the land be restored to a reasonably fit state for agriculture.

It is intended to proceed wherever possible by agreement, and the compulsory rights order when used will give the Coal Board the right for a maximum of ten years to use the land for opencast mining. In moving the second reading, the Paymaster-General, Mr. R. Maudling, said there would be a continuing need for opencast coal for a considerable period: about 160 million tons of coal had been produced by this method from 109,000 acres, 13·5 million tons of this in 1957, and the need was generally but reluctantly accepted by the House; though Mr. Maudling, and Mr. A. Robens for the Opposition, alike recognized the damage done to amenity and agriculture and our duty to hand on the land in a better and not a worse condition.

While Mr. G. Nabarro condemned opencast mining generally but supported the Bill, Mr. M. Philips Price and Mr. R. Speir pressed more specifically for safeguards and greater attention to amenity both in mining and in restoring the land. In replying on the debate, the Parliamentary Secretary to the Ministry of Power, Sir Ian Horobin, urged that, given the need for opencast mining, while the provisions of the Bill were not perfect, they were probably the best we could make. The vital question of amenity had not been overlooked and would be permanently in the minds of the Ministers who had to administer the Act. Improvements could possibly be made during the Committee stage and compensation would no longer be arbitrary.

ANIMAL HEALTH IN GREAT BRITAIN

ANYONE interested in the health of domesticated animals and in their transit to and from Great Britain should read the "Report on the Animal Health Services in Great Britain 1956" (H.M.S.O., London, 6*s*. net), which includes a report on proceedings under the Diseases of Animals Act, 1950. The outstanding features of the report are, on the debit side, the high incidence, during 1956, of foot and mouth disease and anthrax, and the increase of fowl pest; but these liabilities were offset by the steady progress of the Ministry of Agriculture's scheme for the eradication of tuberculosis from cattle in Great Britain, by the demonstration by the Ministry's veterinarians in the Isle of Wight that warble fly disease can be substantially reduced by co-operation between the veterinarian and the farmer, and by the evidence provided in the report of the very wide range of research that is being devoted to the diseases of domesticated animals.

The year 1956 was the worst year for foot and mouth disease since the widespread outbreaks of 1951 and 1952. In 1956 there were 162 outbreaks, but these were confined to England and Wales. Of the 162 outbreaks, thirty-two, which had no known connexion with other outbreaks, were attributed either to swill or to imported meat, bones or meat wrappers, and it was concluded that the disease came from the Continent. It was necessary to slaughter 10,547 cattle, 13,123 sheep, 4,793 pigs and 42 goats, and compensation paid amounted to £824,658.

Anthrax also increased during 1956, although the average mortality from this disease continued to be very low. The disease was very widespread and Yorkshire was especially severely affected. Circumstantial evidence suggests that the outbreaks were caused by imported concentrated foodstuffs, though the infection could not be traced to any particular ingredient of these.

Swine fever, on the other hand, showed a decline of nearly 50 per cent during 1956, when there were only 741 outbreaks, the lowest figure since 1950. In November 1956, the Swine Fever (Infected Areas Restrictions) Order came into force, the object of which is to make possible the speedy imposition of restrictions on the marketing and movements of pigs in areas in which swine fever is prevalent. Fowl pest increased during 1956 and involved the destruction of 1,205,181 birds and 1,005,023 hatching eggs at a cost of £1,371,710 in compensation. Of the 956 outbreaks of this disease, 550 occurred among the dense poultry population of Lancashire, while 121 occurred in Lincolnshire and 84 in Essex; but twenty-one English counties and the whole of Scotland were free from this disease.

A review of suggestions for the control of warble fly led to the conclusion that, until a dressing can be found that will kill the maggots of this fly while they are in the bodies of cattle, the only method of control is to achieve greater compliance with the Warble Fly (Dressing of Cattle) Order of 1948, and a campaign for this purpose was conducted, which included the showing of a film and announcements by poster, in the Press and on the radio. The fine summer of 1955 favoured the laying of eggs by the warble fly on the hairs of cattle, and measures were taken to meet the expected increase in 'warbles' which occurred in 1956. There are in the Isle of Wight about 600 herds of cattle, and the report shows that, as a result of the work of the Ministry's veterinarians, the numbers of herds in the island completely free from warble infestation were 97 in 1954, 374 in 1955 and 500 in 1956, with a corresponding reduction each year in the numbers of individual animals affected. A considerable degree of control has thus been effected by means of effective dressings applied at the right time and by co-operation between the veterinarians and the farmers.

An important section of the report describes the good progress that has been made towards the complete eradication of tuberculosis from British cattle. The Tuberculosis (Attested Herds) Scheme, started in 1935, is entirely voluntary, and the report shows that, by the end of 1956, there were 7 million attested cattle in Britain, representing 67 per cent of the total. A map shows the attested areas in the west of Scotland, the Lake District and south and mid-Wales as they existed on January 1, 1957, and the areas in which free tuberculin tests have been available in 1955 and 1956. These include north Wales, an area south of the Lake District and the counties between the Devon border and the east coast of Kent. The testing of cattle is supported by veterinary detection of tuberculous cows liable to infect the milk supply, though these are now rarely found.

Another section of the report describes the work being done on the incidence of *Brucella melitensis*, which causes human Malta fever in the Mediterranean area. This organism has been found either in milk or in the aborted fœtuses of cows, on forty-two farms in Britain, but there is no evidence that it has ever caused human illness in the United Kingdom. The slaughter of cattle infected with it has therefore been discontinued. It is not known why this organism, which is a near relative of *Brucella abortus*, the cause of contagious abortion in cattle (Bang's disease), should cause human illness in the Mediterranean area but not in Britain.

The very detailed regulations designed to protect animals in transit to and from the United Kingdom are emphasized in the report, which discusses, with valuable statistics, the export and import of horses, asses, mules, pigs and cattle. A Government inquiry into the export of cattle to the Continent was initiated in 1957, from which developments may be expected in the next report.

The report also describes the wide range of research that is going on at the Ministry's centres of research and veterinary investigation. This research includes studies of every disease or infection that may be encountered in Britain and some that are found elsewhere.

REDUCTION OF ORGANIC HYDROPEROXIDES BY MICRO-ORGANISMS AND ANIMAL TISSUES

By DR. D. M. UPDEGRAFF and DR. F. A. BOVEY

Minnesota Mining and Manufacturing Co., Saint Paul 6, Minnesota

DURING the course of investigations of the bactericidal and bacteriostatic action of organic hydroperoxides, it was observed that 0·01 per cent solutions of several hydroperoxides, including *t*-butyl, *p*-menthane and cumene hydroperoxide, in nutrient media, inhibited the growth of *Escherichia coli* and *Bacillus subtilis* only temporarily. Analysis of the cultures showed that the hydroperoxide had disappeared less than 24 hr. after growth began. The known peroxide-decomposing enzymes, catalase and peroxidase, are not reported to decompose the peroxides employed here, but only methyl and ethyl hydroperoxides in addition to hydrogen peroxide itself, and it therefore appeared to be of interest to investigate this reaction further.

The concentration of hydroperoxide in bacterial cultures was determined directly with a manual polarograph, using a voltage of 1·0 V. vs. sat. calomel electrode; calibration curves showed that the waves for all the peroxides employed were fully developed at this voltage. Bacteria were grown on the surface of tryptone–glucose–yeast extract agar, harvested in 0·1 *M* *p*H 6·9 phosphate buffer, centrifuged down, and resuspended in fresh phosphate buffer.

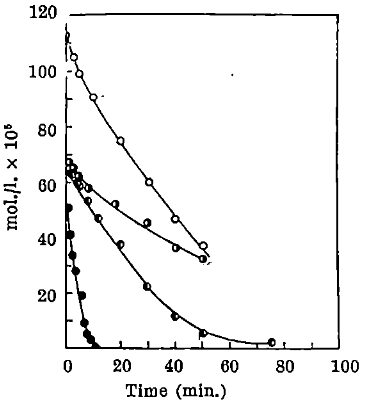

Fig. 1. Decomposition of organic hydroperoxides by *E. coli*. ○, *t*-butyl hydroperoxide; ◑, *p*-menthane hydroperoxide; ◐, cumene hydroperoxide (2×10^9 cell/ml.); ●, cumene hydroperoxide (10^{10} cells/ml.)

Plant and animal tissue homogenates were prepared in the same buffer by means of a Virtis homogenizer.

Determinations of catalase activity were also carried out on these same suspensions, suitably diluted when necessary, by measuring the rate of disappearance of hydrogen peroxide polarographically at 1·5 V. As hydrogen peroxide is decomposed by catalase, the oxygen produced gives a wave which almost exactly replaces that of the disappearing hydrogen peroxide, and it was therefore ordinarily necessary to sweep out the oxygen with a stream of nitrogen before measuring the hydrogen peroxide wave. If this was not done, the current at 1·5 V. underwent little or no change. In many cultures, however, the endogenous uptake of oxygen was at least as fast as the decomposition of hydrogen peroxide by catalase, and in these circumstances, nitrogen sweeping could be omitted. Peroxidase activity was measured similarly in the presence of 0·04 *M* pyrogallol; this measurement is grossly inaccurate unless the peroxidase activity is at least comparable to the catalase activity, since the two enzymes compete for the hydrogen peroxide. If the catalase and peroxidase activities are comparable, the peroxidase activity is given approximately by the increase in the rate of disappearance of hydrogen peroxide when pyrogallol is added. When endogenous respiration is very small or zero, peroxidase activity can also be measured as the apparent rate of decrease of the hydrogen peroxide wave at 1·5 V. in the presence of pyrogallol, for oxygen is not produced when hydrogen peroxide is decomposed by peroxidase. Since the measurement of peroxidase activity is often rather uncertain, the reporting of a zero activity only means that it was too small to be measurable by these means, and also that no visible purpurogallin colour developed in the culture on adding pyrogallol.

Control experiments established that beef-liver catalase (Armour), even in concentrations as high as 0·075 K.U. per ml., does not decompose the organic hydroperoxides employed in this study, either in the presence of cells (made inactive by heating) or in the buffer alone. However, 10^{-3} times this concentration of the same catalase preparation rapidly decomposed hydrogen peroxide. Likewise, horseradish peroxidase has no effect in buffer or cell suspensions containing 0·04 *M* pyrogallol, or in cell suspensions without pyrogallol.

In Table 1 are presented the rates of decomposition of cumene hydroperoxide, purified by preparation of the sodium salt, by 17 species of bacteria, yeasts, moulds, preparations of mammalian tissue, and plant tissue. The bacterial activities are reported as moles per minute per cell ($\times 10^{18}$), whereas the activities of the other systems are given only qualitatively. Catalase activities are reported in all cases, and peroxidase activities for eleven systems. Fig. 1 illustrates the rate of decomposition of cumene, *t*-butyl and *p*-menthane hydroperoxides by *Escherichia coli* suspensions. Initial peroxide concentrations were usually made approximately $6{\cdot}5 \times 10^{-4}$ *M*. The rates are neither exactly zero nor first order, but are intermediate and vary somewhat with the peroxide concentration and the cell count. It can be seen that cumene hydroperoxide is decomposed by fourteen of the seventeen species of bacteria tested, by the yeasts and by the animal tissues, but not by the mould, *Aspergillus niger*, or the plant tissues. Catalase activity is usually accompanied by cumene hydroperoxide-decomposing activity, but this is not necessarily so, as these three last-mentioned examples show. On the other hand, no clear evidence was obtained that cumene hydroperoxide-decomposing activity can occur without accompanying catalase activity, although there is no quantitative correlation between these activities. Consequently, anaerobic organisms, which usually show no catalase activity, show likewise no activity toward cumene hydroperoxide. A possible exception is the obligate anaerobe *Veillonella gazogenes*, which shows very strong cumene hydroperoxide-decomposing activity and only very weak catalase activity. This last observation strongly suggests that the cumene hydroperoxide-decomposing system has little or no effect on hydrogen peroxide.

Table 1. CUMENE HYDROPEROXIDE DECOMPOSING ACTIVITY IN MICRO-ORGANISMS AND TISSUES

Organism or tissue	Activity, mol./min./cell × 10^{18}		
	Cumene hydroperoxide decomposing activity	Catalase activity	Peroxidase activity
1. *Micrococcus pyogenes* var. *aureus*	4	3	0
2. *Escherichia coli*	5	50	0
3. *Erwinia carotovora*	0·9	5·3	0
4. *Bacillus subtilis*	7	6·2	0
5. *Streptococcus faecalis*	0	10	0
6. *Leuconostoc mesenteroides*	0	0	0
7. *Pseudomonas aeruginosa*	4	4	1
8. *Serratia marcesens*	2	24	0
9. *Alcaligenes viscosus*	4·2	5	–
10. *Alcaligenes faecalis*	1·1	2·7	5·3
11. *Aerobacter aerogenes*	0·47	7·5	–
12. *Neisseria catarrhalis*	0·83	4·1	–
13. *Proteus morganii*	0·45	86	–

24. Hog kidney (acetone powder)	strong	strong	–
25. Hog pancreas (acetone powder)	strong	strong	–
26. Spinach (fresh)	0	strong	–
27. Oak leaves (fresh)	0	strong	–

+ Not tested by us, but known from the literature to be positive.
– Not known.

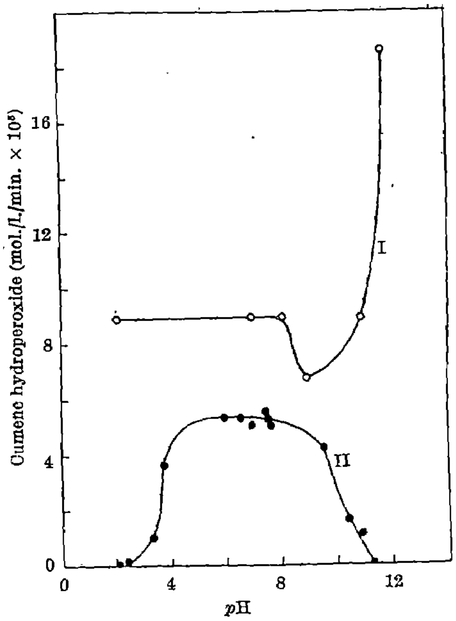

Fig. 2. Effect of pH on rate of reduction of cumene hydroperoxide. O, ascorbic acid in 0·1 *M* phosphate buffer; ●, *E. coli* and glucose in 0·1 *M* phosphate buffer

It appears likely that the hydroperoxide-decomposing activity of animal cells is to be attributed to ascorbic acid, which is known to be widely distributed in mammalian tissues, and which is capable of rapidly decomposing cumene hydroperoxide even when both are at low concentrations. Curve I of Fig. 2 shows the initial rate of reduction of cumene hydroperoxide, initially 0·00055 *M*, by initially 0·00095 *M* ascorbic acid in 0·1 *M* phosphate buffer, as a function of pH. (Trace amounts of copper are required to achieve an appreciable rate; it is well known that the autoxidation of ascorbic acid likewise requires copper.) This behaviour is in contrast to the broad bell-shaped curve of dependence of the rate of decomposition by *E. coli* on pH (Curve II, Fig. 2). The activity of mammalian cells is also distinguished from that of bacteria or of yeast in being undiminished by heating for 10 min. at 100° C.; the activity of *E. coli* and of baker's yeast is destroyed by heating to 70° for 1 min.

The activity of *E. coli* was found to be dependent on the presence of cofactors found in yeast extract. It has been observed that 'old' cells of *E. coli*, that is, those harvested after more than 24 hr. growth, show greatly reduced or no activity toward hydroperoxides, but that activity can be restored by the addition of a dilute solution of yeast extract. More than fifty different substances of biochemical interest were then tested, and their potencies in restoring activity, measured as initial rate of cumene hydroperoxide decomposition, were determined. Many carbohydrates were active, including mannitol, glucose, galactose, mannose, sucrose, arabinose, fucose, glucosamine, glucuronic acid, glucuronolactone, galacturonic acid, ribose, rhamnose, acetyl-α-amino glucose, fructose, dextrin and glucose-1-phosphate. Sodium formate and hydrogen were also active. Compounds tested and found inactive included the following carbohydrates and related compounds: α-methyl glucoside, α-methyl mannoside, lactose, pentaerythritol, 2,3-butylene glycol, trimethylene glycol, sorbose, dulcitol, sorbitol, glucose-6-phosphate, fructose-6-phosphate, fructose-1,6-diphosphate, phosphoglyceric acid, dihydroxyacetone, dehydroascorbic acid, glycerol and sodium pyruvate; also inactive were: all the known B vitamins, cysteine, reduced glutathione, and all the common amino-acids normally occurring in proteins. In buffer alone, only ascorbic acid, of all the compounds tested, was capable of decomposing cumene hydroperoxide in the dilute solutions in which they were tested.

Experiments in which glucose was added to an 'old' and inactive *E. coli* suspension showed that approximately 2·7 moles of peroxide were reduced per mole of glucose added. The added carbohydrate does not thus take a merely catalytic role, but is consumed at a rate which is of the same order of magnitude as that of the peroxide. In pH 6·9 buffer alone, one mole of ascorbic acid was found to reduce two moles of cumene hydroperoxide.

The effective substances are those which can be readily fermented by *E. coli*, but it is not clear whether the Embden–Meyerhof glycolytic system is involved in view of the very broad pH range over which rapid reaction of cumene hydroperoxide can be observed. It appears possible that bacteria and many other organisms and tissues contain an enzyme system capable of converting fermentable carbohydrates to an intermediate form which can react rapidly with organic hydroperoxides. Ordinarily, this intermediate may occur in equilibrium at very low concentrations, and its existence may become evident only when organic hydroperoxides or other strong oxidizing agents are present. In this connexion, the dienol glucose reported by Nath and Bhattathiry[1] may be recalled.

The activity of formate and of molecular hydrogen may be attributed to the hydrogenlyase and hydrogenase systems, respectively[2]. The fact that hydrogen and formate give a lower rate of cumene hydroperoxide reduction than some of the carbohydrates is probably attributable to the extremely low solubility of hydrogen in water. Formate could be rapidly converted to hydrogen and carbon dioxide, and some of the hydrogen might be lost from the cell into the nitrogen atmosphere above the liquid.

The reduction of organic hydroperoxides might be accomplished by an enzyme system of broad pH

Table 2. RELATION BETWEEN CARBOHYDRATE FERMENTATION AND COFACTOR ACTIVITY

Organism	Fermentation of carbohydrate listed			Cofactor activity of carbohydrate listed		
	Glucose	Glycerol	Inositol	Glucose	Glycerol	Inositol
Micrococcus pyogenes	*A*	*A*	0	+	+	0
Alcaligenes faecalis	0	0	0	0	0	0
Alcaligenes viscosus	0	0	0	0	0	0
Pseudomonas aeruginosa	0	0	0	0	0	0
Proteus morganii	*AG*	?	0	+	+	0
Aerobacter aerogenes	*AG*	?	*AG*	+	0	+
Escherichia coli	*AG*	0	0	+	0	0
Saccharomyces cerevisiae	*A*	–	–	0	–	–

A, acid (or carbon dioxide) only produced; *G*, hydrogen gas produced; ?, fermentation reaction variable or not known range capable of producing formate or hydrogen from carbohydrate, accompanied by a system (hydrogenlyase or hydrogenase) capable of transferring hydrogen from formate or molecular hydrogen to the hydroperoxide. Such a system could only be active in carbohydrate-fermenting, hydrogenlyase-positive organisms such as *E. coli* and the other Enterobacteriaceae. Yeasts and non-carbohydrate-fermenting bacteria such as *Alcaligenes faecalis* and *Pseudomonas aeruginosa* must reduce hydroperoxides by quite a different mechanism. In support of this suggestion, experiments were performed with a number of micro-organisms, as shown in Table 2. It will be noted that in every case where an organism was known to ferment a given carbohydrate, that carbohydrate served as a cofactor for the reduction of cumene hydroperoxide. Conversely, where a carbohydrate was known not to be fermented, no cofactor activity was found. *Micrococcus pyogenes* produces acid but no gas from glucose and glycerol, and hence shows no hydrogenlyase activity; nevertheless, these compounds show cofactor activity with *M. pyogenes*.

Probably, as in the case of methylene blue reduction, a wide variety of different mechanisms may be found, in different types of organisms and tissues, for the reduction of organic hydroperoxides.

The significance of organic hydroperoxides in the metabolism of bacteria is uncertain. Probably they do not ordinarily play an important part. However, Imelik[3] has suggested that the initial product of the oxidation of hydrocarbons by bacteria is a hydroperoxide. It further appears likely that organic peroxides may play a part in the effects produced by high-energy radiation. Thus, Scholes, Weiss and Wheeler[4] were able to detect hydroperoxides in ribonucleic and deoxyribonucleic acids exposed to ultra-violet radiation, and the formation of organic peroxides in proteins exposed to high-energy radiation has been reported[5]. We suggest that the peroxide-decomposing system we have described may be important in protecting the cell against radiation-induced damage.

THE AGROTYPE CONCEPT IN TEA TAXONOMY

By Dr. W. WIGHT

Scientific Department, Indian Tea Association, Tocklai Experimental Station, Cinnamara

THE special taxonomic problems posed by the tea plant are not generally known, nor was their satisfactory resolution apparent when they were first investigated at Tocklai. A classical system of nomenclature does not deal adequately with the cultivated tea plant[1].

Populations of tea bushes, nominally referred to[2] as *Camellia sinensis* L., which are used for the manufacture of tea, have a life of half a century or more. In India they are raised from seed produced in orchards of phenotypically mixed trees of the cross-bred origin described by Hunter and Leake[3]. This origin probably stems from earlier species hybrids[2]. A seed orchard is perennial, and thus genetically similar progenies of various ages come to be widely dispersed among numerous tea estates; but the orchard itself may have been forgotten or destroyed. The relative frequency of phenotypes differs greatly between progenies of disparate orchards.

Shoots from all bushes in a population are plucked and manufactured in bulk. Provided that the overall impression of 'quality' is satisfactory and the gross yield sufficiently high, wide phenotypic variation affecting *inter alia* yield and quality may be tolerated, and may possibly be a safeguard against excessive incidence of pests and diseases. There are big yield (and quality) differences between disparate progenies, yield per unit ground area being an essential criterion of agricultural efficiency.

Pure lines have not been used and are likely to have an impracticably low vigour: first-generation crosses between clones are known[4], but have not come into general use. There is accordingly great practical need for an efficient method of defining and discriminating between the mixed populations in current cultivation. Without this, it is impossible to investigate satisfactorily the influence of cultural practices and local conditions on yield, while even the most precise analysis of tea made from undefined populations is necessarily restricted in meaning.

Both quality of the made tea and yield of plucked shoots from which the tea is made differ between phenotypes; but in practice each of these attributes of individual phenotypes is automatically integrated into a single population value by the normal processes of bulk manufacture, and the integrated value becomes the yardstick by which the effect of manures and cultural treatments is measured. Investigation would be facilitated if there were important differentiating features of the phenotypes that could be integrated into a single numerical value by which the population could be given position in a taxonomic array.

To connote the concept of an integrated or average phenotype numerically defined, we have for some years used the term 'agrotype', originally proposed by Gregor[5] in connexion with the typification of crop plants. He suggested that crop populations (agrotypes) should be defined by stating the mean values and the variability of the characters, including characters of agricultural importance, chosen for typification.

A population average is possible provided the constituent individuals can be given numerical values corresponding to their expressions of the typifying feature. The condition is readily satisfied by number of unit organs exhibited, frequency of stamens, for example, or frequency of a specified type of cell. Where such a frequency is the only criterion of a phenotype employed, the agrotype of a population is simply defined by the mean frequency with its standard error.

The purpose of the present article is to show that frequency of calcium oxalate crystals in a specified

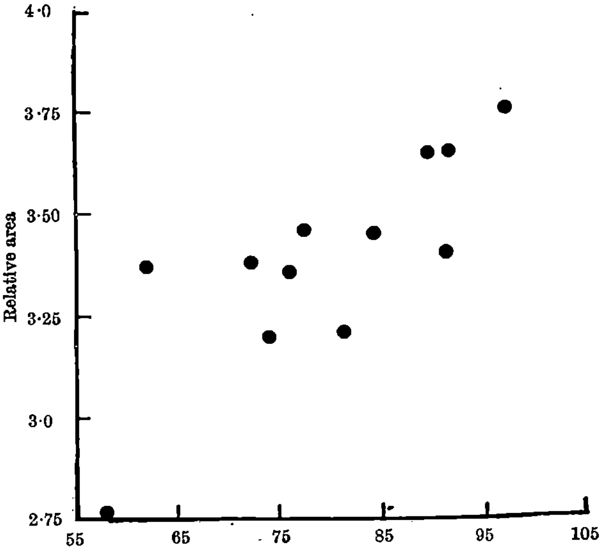

Fig. 1

region of the plant is a valuable criterion for the typification of tea populations. The crystals are in fact druses, and as only one druse occupies the lumen of a cell as seen in cross section, crystal frequency is a frequency of unit organs (cells) characterized by a particular set of chemical reactions.

Crystal frequency has been defined as total number of crystals in the phloem parenchyma of a complete cross-section of the leaf petiole[6]. Statistical analysis by Barua[7] shows that errors of counting can be kept within narrow limits. Crystal frequency has been shown to differ significantly between clones raised from seedlings of chance origin[6]; and in view of the cross-bred nature of commercial tea seed orchards, it seems likely that every tea seedling has its characteristic crystal frequency. Further, different tea populations in cultivation have been shown to differ significantly in mean crystal frequency[6].

Other mean attributes of a population have been shown to be related to the mean crystal frequency. There is a positive correlation with the number of standard shoots that can be obtained by repeated cropping or plucking[6]. This relation is subject to large seasonal and sampling errors. A similar but closer relation (shown in Fig. 1) holds between mean crystal frequency of a population and mean surface area of a bush ($r = +0.74 : P < 0.01$). The values shown in Fig. 1 are of relative area, square of the bush radius in feet (mean of two diameters). The Indian system of pruning and plucking results in a flat horizontal surface[8], and the method indicated has been shown to give a satisfactory measure of relative bush area.

The foregoing observations show that crystal frequency is indicative of a nature of growth (growth form) that must have an important bearing on the yield of a tea plantation: they suggest that crystal frequency may be closely related to a frequency of important genes.

In order to study the inheritance of the factors determining crystal frequency, it has been necessary to examine cross-bred progenies, since satisfactory progenies by self-pollination are difficult to obtain. Six cross-bred progenies were obtained by controlled pollination within pairs of parents indicated in Table 1. The parents originated as seedlings from commercial orchards the cross-bred nature of which has already been noted. Depending on the amount of experimental seed obtained, varying numbers of progeny plots, each of twenty-four seedlings, were established. Mean crystal frequencies for each progeny were determined by taking one leaf from each of five seedlings, chosen at random, in each plot, in accordance with the sampling method used in earlier investigations[6]. Analysis of variance showed the progenies to differ significantly in respect of mean crystal frequency ($P < 0.001$). Seedling differences within progenies were found to be significant ($P < 0.001$) when tested against the variation shown by replicate microtome sections of the same leaf. The more stringent test, against field variation of vegetative replicates of the seedlings, has not yet been carried out, but real differences between seedlings would undoubtedly be expected.

Table 1. Crystal Frequency of Progenies: June 1956

Mating	Parents ♀	♂	Number of plot repeats of progeny	Crystal frequency of a mean plant of the progeny
1	19/29/13 ×	19/35/2	7	101·3
2	19/35/2 ×	19/31/14	2	99·6
3	19/29/13 ×	19/31/14	5	100·8
4	19/37/2 ×	19/39/7	5	60·0
5	19/37/2 ×	19/36/15	2	50·3
6	24/7 ×	24/6	3	58·8
7	19/36/15 ×	19/39/7	5	39·2

Estimates of parental crystal frequency, given in Table 2, were obtained by sampling vegetative replicates, one leaf being taken from each of twelve plants, chosen at random, within a set of forty-eight vegetative replicates that had been produced from each parent.

At the time of the crystal counts the progenies were all the same age, 6 years, and the vegetative replicates of the parents were all 9 years old except for mating 6 (8 years). Parents at the time of vegetative propagation were all 30 years old except for mating 6 (10 years). All parental clones had received a common treatment, similarly all progenies; but there had earlier been differences of pruning and plucking between parents and progenies. Practical management of the plots had made it impossible to avoid a difference of about three months between the age (following annual prune) of parental shoots and those of their progeny; but it is our experience that this would have a negligible effect on the relative crystal frequencies.

Table 2. Crystal Frequency of Parents determined from Vegetatively Propagated Replicates in May 1956

Parent	Mean crystal frequency	Standard error	Name of orchard and year of seed origin of parent	Location of orchard lat. N.	long. E.
19/37/2	98·8	4·64	Bhatkhowa, 1917	26°40′	89°30′
19/35/2	128·1	4·63	Subong, 1917	24 55	92 50
19/29/13	117·9	3·91	Cinnamara, 1917	26 45	94 15
19/39/7	48·5	2·77	Huloonguri, 1917	26 40	94 25
19/31/14	108·9	3·95	Jaipur, 1917	27 15	95 25
24/6	77·4	5·12	Bazaloni, 1938	27 25	95 30
24/7	40·6	2·78	Bazaloni, 1938	27 25	95 30
19/36/15	26·4	1·78	Jadoo, 1917	27 30	95 35

Table 3. Crystal Frequencies of Parents and Progeny

Mating	Mean value of the two parents	Mean value of the progeny
1	123·0	101·3
2	118·5	99·6
3	113·4	100·8
4	73·6	60·0
5	62·6	50·3
6	59·0	58·8
7	37·4	39·2

The mean crystal frequencies of the two parents for each mating and the mean frequencies of their progeny are given in Table 3 and the correlation is shown in Fig. 2. The correlation coefficient of + 0·98 ($P < 0{\cdot}001$) shows that the crystal frequencies of progenies can be predicted from their parents with some precision. More recent observations on matings indicate that the relation continues to hold for matings between parents of even lower crystal frequency than any shown in the figure.

The foregoing observations show that the frequency of calcium oxalate crystals is an important method of defining tea agrotypes. Such agrotypes do not bear a simple relation to the varietal types of classical nomenclature; but in our experience crystal frequency is a necessary definition of tea plants for many theoretical and practical purposes. It is of similar importance as a definition of the processed shoots sold as dry tea. The frequency of calcium oxalate crystals fixes the position of individuals and populations on a scale which has a genetic basis. Use of such a scale simplifies investigation of problems connected with heterogenous populations.

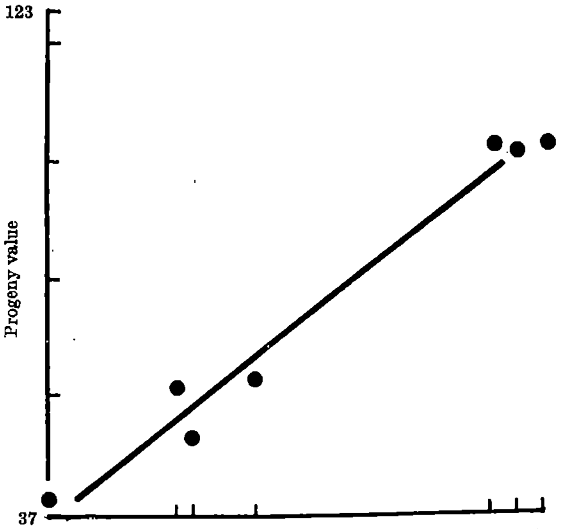

Fig. 2

I am indebted to Dr. J. W. Gregor and his staff when at Craigs House, Corstorphine, for many helpful discussions on the nature of plant populations, and to Prof. E. J. Maskell for valuable comments on presentation of the paper.

INTERMEDIATES AND COMPETING REACTIONS IN THE PHOTODESTRUCTION OF INDOLEACETIC ACID

By PETER M. RAY* and GEORGE M. CURRY†
Biological Laboratories, Harvard University

THE changes in ultra-violet spectrum during photodestruction of aqueous solutions of indole-3-acetic acid by monochromatic ultra-violet light of 280 mμ, in air, have been followed in parallel with the decrease in Salkowski reaction intensity and in *Avena* coleoptile growth-promoting activity. The changes in spectrum lagged behind the disappearance of indole-3-acetic acid, as estimated by either of the latter methods, in such a way as to indicate the accumulation of an intermediate having an ultra-violet spectrum similar to that of the acid. This intermediate, which will be called *M*, appears to be stable in the absence of radiation, and it undergoes further photodestruction to give the spectrum shown in curve 3 of Fig. 1. When indole-3-acetic acid labelled with carbon-14 in the 2-carbon of the indole ring was irradiated, the tracer appeared in part in a chromatographic spot (*M'*, ref. 1) of R_F somewhat greater than indole-3-acetic acid, and which gave a weak pink nitrite reaction. The amount of material in this spot (as estimated from its radioactivity), at different times during the course of the reaction, corresponded approximately with the amount of *M* which was calculated, from the spectrophotometric changes, to be present; it disappeared by the time all the indole-3-acetic acid had been destroyed. The chromatographically detected intermediate *M'* may thus be the substance *M* indicated by the spectrophotometric observations, though this remains to be proved. It appears to be the same as substance '*E*' detected chromatographically by Fischer[2] in the photo-oxidation of indole-3-acetic acid which he regarded as indole-3-glycolic acid. In our hands, however, synthetic indoleglycolic acid ran at an R_F lower than indole-3-acetic acid[3]; the intermediate *M'* appears to be neither indoleglycolic nor indoleglyoxylic acid. Its identity is not yet established.

The spectrum of the final product (Fig. 1, curve 3) shows unmistakable similarity to the spectrum of indole-3-carboxaldehyde (indolealdehyde) shown in curve 2 (Fig. 1). This compound could readily be detected on chromatograms of the reaction product[1],

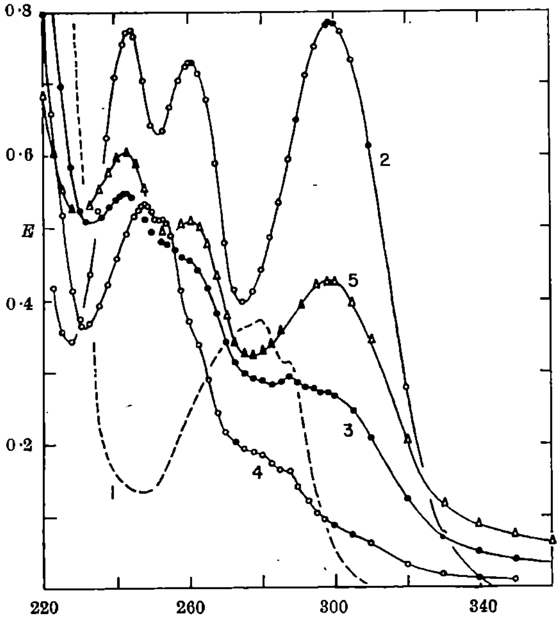

Fig. 1. Ultra-violet spectra (6·9 × 10^{-5} *M* solutions) of indole-3-acetic acid (curve 1), indole-3-carboxaldehyde (curve 2), and photodestruction products of indole-3-acetic acid (curves 3 and 4) and indoleglycolic acid (curve 5). Curve 3, irradiation of indole-3-acetic acid at 280 mμ (90 min., 5,600 ergs/sec.) or for 4 min. at 10 cm., from an unfiltered General Electric *H*85*C*3 100-watt mercury lamp (quartz). Curve 4, irradiation of indole-3-acetic acid at 302 mμ (180 min., 16,800 ergs/sec.) or for 95 min. at 10 cm., from an unfiltered General Electric *AH*-5 250-watt mercury lamp (glass). Curve 5, irradiation of indoleglycolic acid for 4 min. at 10 cm. from the *H*85*C*3 lamp. Photodestruction was carried out using 1·7 ml. of solution in a quartz cuvette of 1-cm. light path, as described previously (ref. 6) except that slit-width was 3·0 mm.

and the spot of colour corresponded with a peak of radioactivity when 2-labelled indole-3-acetic acid was used as substrate. Although these observations confirm the finding of Fischer[2] that indolealdehyde is a product, it can be seen from curve 3 (Fig. 1) that other light-absorbing materials than indolealdehyde were present in the product, and that taking these into account, indolealdehyde could have been formed at most in about 25 per cent yield from indole-3-acetic acid. The remaining products ran close to indolealdehyde on chromatograms, and were presumably neutral substances also. They were not products of photodestruction of indolealdehyde, because the latter itself was relatively little affected by a radiation dose sufficient to convert an equal amount of indole-3-acetic acid entirely into the products of curve 3 (Fig. 1). They appear to be formed from *M* along with indolealdehyde.

Irradiation of synthetic indoleglycolic acid gave the spectrum shown in curve 5 (Fig. 1). This indicates a considerably higher yield of indolealdehyde than from indole-3-acetic acid, perhaps approaching 50 per cent of stoichiometric, but there are evidently other light-absorbing materials present. Comparison of curves 3 and 5 (Fig. 1) indicates that were indoleglycolic acid an intermediate in photo-oxidation of indole-3-acetic acid, it could be formed initially only in partial yield. No direct evidence for its occurrence in photo-oxidation of indole-3-acetic acid has been obtained.

It was found, surprisingly, that when the wave-length of irradiation was varied, the spectrum of the final product also varied, even though phenomena indicative of the formation of *M* were still observed. The spectrum of the product formed by irradiation at 302 mμ or 313 mμ (curve 4) is almost identical with that of the enzymatic oxidation products of indole-3-acetic acid[4]. At 289 mμ and 297 mμ, spectra intermediate between curves 3 and 4 resulted. Neither of these products was convertible into the other by irradiation at any wave-length, so neither of them constitutes an intermediate step in the formation of the other. However, when irradiation intensity at 280 mμ was decreased, a portion of the final products also appeared in the form of curve 4. The proportion of the latter product formed at different irradiation intensities corresponded closely with what could be predicted from the kinetics of competing light- and dark-reactions acting on a second intermediate, *N* :

$$\begin{tikzcd}
 & & & \text{indolealdehyde + other products} \\
\text{Indole-3-acetic acid} \arrow[r, "k_1 I"] & M \arrow[r, "k_2 I"] & N \arrow[ur, "k_3 I"] \arrow[dr, "k_4"'] & \\
 & & & B \text{ (enzyme reaction products)}
\end{tikzcd}$$

Curve 3 corresponds to a light intensity *I* so great that essentially all of *N* is decomposed by the light-reaction governed by k_3. The extinction of *N* is evidently negligible at 302 mμ and 313 mμ, where indole-3-acetic acid still absorbs slightly and undergoes photodestruction, so that only *B* is formed. That *N* is not indoleglycolic or indoleglyoxylic acid is shown by the fact that these are stable, under the present conditions, in the absence of radiation. It was found afterwards that the difference in reaction products described above can be obtained simply by comparing the effects of mercury lamps with quartz (curve 3) and glass (curve 4) envelopes.

These observations indicate that the photo-oxidation process is complex, and preclude its being formulated simply as a stepwise conversion of indole-3-acetic acid into indoleglycolic acid, indoleglyoxylic acid, and indolealdehyde. At the same time they indicate a much closer chemical relationship between photodestruction and enzymatic oxidation of indole-3-acetic acid than has hitherto seemed likely, and complement nicely the recent finding of Stutz[5] that the enzymatic reaction can be diverted to the formation of indolealdehyde when cytochrome *c* and a cytochrome oxidase preparation are present in addition to 'indole-3-acetic acid oxidase'.

We wish to thank Prof. K. V. Thimann for his interest in this work, Dr. Bruce B. Stowe for synthesis of indolealdehyde and indoleglyoxylic acid, and Dr. M. D. Armstrong for the sample of indoleglycolic acid. The work was supported in part by grants to Prof. K. V. Thimann from the American Cancer Society on recommendation of the Committee on Growth, and from the National Science Foundation (*NSF*–G182).

STUDIES OF UROCANIC ACID

By ROBERT H. FEINBERG[*] and PROF. DAVID M. GREENBERG

Department of Physiological Chemistry, University of California School of Medicine, Berkeley

Intermediate Products in the Enzymatic Degradation of Urocanic Acid

UROCANIC acid (β-imidazoleacrylic acid) is the first intermediate formed in the catabolism of histidine to glutamic acid by mammalian liver[1]. The only other intermediate which has been well characterized is N-formiminoglutamic acid.

In order to study how the imidazole ring is opened, purified beef liver urocanase was allowed to act on α-^{14}C-urocanic acid (prepared enzymatically from α-^{14}C-histidine). The enzyme was purified 30-fold by a procedure which included adsorption with bentonite, precipitation with ammonium sulphate and fractional extraction of the ammonium sulphate precipitate. The enzyme activity was assayed by the spectrophotometric method of Tabor and Mehler[2].

Upon fractionation of the radioactive incubates, evidence was found for the formation of two products, one having an ultra-violet absorption peak at approximately 264 mμ (I), and the other (II) having an end-absorption. Comparison by paper chromatography showed that neither of these products was N-formiminoglutamic acid (Table 1), nor was N-formiminoglutamic acid found in any of the incubation mixtures, even when the incubation was allowed to proceed until no urocanate remained.

Spots of I and II on paper gave no colour when sprayed with Pauly's diazo reagent or with alkaline ferricyanide-nitroprusside reagent (an amidine test)[3]. Compound II was found to give a delayed ninhydrin reaction upon prolonged heating. It can be separated from I and purified by paper electrophoresis at *p*H 4·6 (Table 1). At this *p*H it is negatively charged, while I is approximately neutral. Synthetic formyl-L-isoglutamine was not separable from II by paper chromatography (with two solvents), or by paper electrophoresis (Table 1). Consequently, II appears to be formylisoglutamine.

Isolation of formyl-D,L-isoglutamine as a product of urocanase action was reported by Oyamada[4]. Formyl-L-isoglutamine has been synthesized and found to be microbiologically inactive[5,6]. Thus, probably it is not on the enzymatic pathway.

Table 1. RELATIVE ZONAL MOVEMENT WITH CHROMATOGRAPHY AND ELECTROPHORESIS ON PAPER

Substance	Chromatography Solvent *A* R_{uro}	Chromatography Solvent *B* R_{uro}	Electrophoresis *p*H 4·6 R_{pic}
Urocanic acid	1·0		0, 0·05
N-formiminoglutamic acid	0·52		0·82
Formylglutamic acid	0·82		
Glutamic acid	0·26		
Formyl-L-isoglutamine	0·93	0·95	0·75
I	0·95		0·01
II	0·91	0·97	0·74

Solvent *A*, propanol–1*N* acetic acid (3 : 1); solvent *B*, *t*-butanol–formic acid–water (14 : 3 : 3)

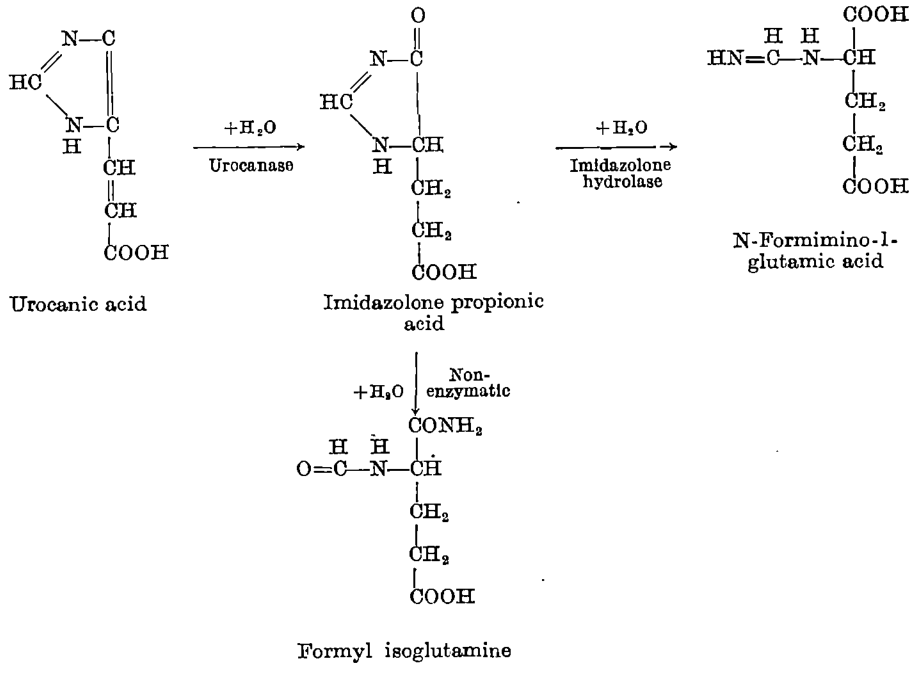
Electrophoresis medium: 0·2 *M* triethyl ammonium acetate. R_{uro} and R_{pic} are movements relative to urocanic acid and picrate, respectively

Formation of I was found to parallel the disappearance of urocanic acid, with no observable time lag. The ultra-violet absorption of I rapidly disappeared when it was mixed with crude liver extract. Neutral solutions of I are unstable at room temperature. Aged solutions of I contained large amounts of II.

The ultra-violet absorption, electrophoretic behaviour and instability of I lead us to propose that it is 4,(5)-imidazolone-5, (4)-propionic acid[7] (see scheme of reactions). The formation of formylisoglutamine by non-enzymatic hydrolysis is consistent with this proposal.

The reactions shown below account for our findings. They are similar to the proposals of others[4,5].

This work was aided by a research grant from the National Cancer Institute (*CY*-3175), United States Public Health Service.



Urocanic acid

Imidazolone propionic acid

N-Formimino-l-glutamic acid

Formyl isoglutamine

Dye Reduction by a Metabolite of Urocanic Acid

Miller and Waelsch[1] have reported that mixtures of urocanate with cat liver urocanase reduce such hydrogen acceptors as 2,6-dichlorophenol, indophenol and ferricyanide. This led them to propose a step involving oxidized urocanate and reduced enzyme as an intermediate of urocanase action.

Our preparation of partially purified beef urocanase when incubated with urocanate and the above dye reduced the dye at a higher rate than Miller and Waelsch reported. Further investigation showed that the dye reduction proceeded rapidly and non-enzymatically in neutralized trichloracetic acid deproteinized incubation mixtures in which urocanate was exhausted. Potassium ferricyanide was used in spectrophotometric studies to show that addition of this hydrogen acceptor caused an immediate reduction in the 264-mμ peak of imidazolone propionic acid presumed to be present in the mixtures.

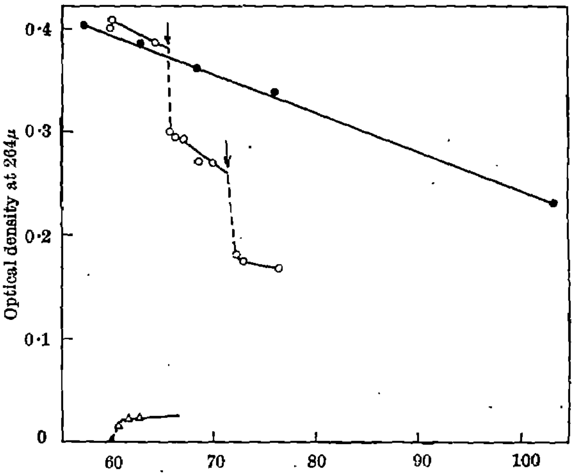

Fig. 1. Effect of addition of ferricyanide on the absorption of incubation mixtures of urocanic acid at 264 mμ.
The incubation mixture contained 0·5 μmole of urocanate, 40 μmoles of phosphate buffer, *p*H 7·1, and 2 mgm. of purified urocanase in total volume of 2·9 ml. Urocanate was exhausted at about 40 min. (in line designated by ○). At the points indicated by arrows, 0·1 ml. (0·05 μmole) of potassium ferricyanide was added; ●, same with no ferricyanide added; △, same with urocanate omitted. Readings are against enzyme blank at 25° C.

The rapid reduction of dye by imidazolone propionic acid indicates that this metabolite is susceptible to oxidation as well as hydrolysis. This suggests that imidazolone propionic acid may be an intermediate of the oxidation of urocanic acid described by Ichihara *et al.*[2].

Our results do not bear out the proposal of Miller and Waelsch that an oxidation product of urocanic acid is an intermediate of urocanase action.

This work was aided by research grants from the National Cancer Institute (*CY*-3175 and *C*-2869C), United States Public Health Service.

DEALKYLATION OF N-ALKYLAMINES BY MODEL SYSTEMS

By JAMES R. GILLETTE, JAMES V. DINGELL and BERNARD B. BRODIE

Laboratory of Chemical Pharmacology, National Heart Institute, National Institutes of Health, Public Health Service, U.S. Department of Health, Education and Welfare, Bethesda, Maryland

A MAJOR pathway of drug metabolism is the oxidative dealkylation of N-alkylamines to yield a primary amine and an aldehyde. This reaction is catalysed by enzyme systems in liver microsomes and requires both reduced triphosphopyridine nucleotide and oxygen[1]. Since microsomes oxidize reduced triphosphopyridine nucleotide to yield triphosphopyridine nucleotide and peroxide-like material, it has been suggested that the peroxide moiety participates in the dealkylation of drugs as well as in their oxidation along other metabolic pathways[2]. However, a clear picture of the precise mechanism of dealkylation is not yet evident.

Unpublished work in this laboratory has shown that the demethylation of monomethyl-4-aminoantipyrine by liver microsomes was inhibited by α,α′-dipyridyl, suggesting the possibility that iron participates in the reaction. Furthermore, preliminary studies demonstrated that methæmoglobin and a hydrogen peroxide generating system catalysed the demethylation of monomethyl-4-aminoantipyrine. These findings have led us to investigate the action of a number of iron-containing model systems in the hope that some insight into the mechanism of microsomal dealkylation might be obtained.

The present communication describes studies with monomethyl-4-aminoantipyrine, N-methylaniline and their dimethyl congeners which demonstrate that a number of iron-containing model systems promote the demethylation of the alkylamines at physiological *p*H and temperature, and that dealkylation may occur by a number of mechanisms.

Three hæmoproteins—methæmoglobin, cytochrome *c* and horseradish peroxidase—were incubated with the amines in the presence of hydrogen peroxide generated by means of glucose and glucose oxidase ('Notatin'). Demethylation, as measured by the amount of formaldehyde trapped by semicarbazide[1], was catalysed by all three systems. As the reaction did not occur in the absence of the hydrogen peroxide

Table 1. DEMETHYLATION OF MONOMETHYL-4-AMINOANTIPYRINE (MMAP) AND 4-AMINOANTIPYRINE (AAP) BY MODEL SYSTEMS

	Formaldehyde from MMAP	Formaldehyde from AAP
Methæmoglobin ($1\cdot4 \times 10^{-5}$ *M*)	(μmoles)	(μmoles)
In air	0·0	0·0
Plus H_2O_2 generating system	2·1	1·1
Cytochrome *c* ($6\cdot2 \times 10^{-5}$ *M*)		
In air	0·0	0·0
Plus H_2O_2 generating system	1·0	0·3
Horseradish peroxidase (1×10^{-6} *M*)		
In air	0·1	0·0
Plus H_2O_2 generating system	2·4	1·2
Hæmatin (1×10^{-3} *M*)		
In air	1·1	0·6
Plus H_2O_2 generating system	1·0	0·6
$FeCl_3$ (6×10^{-3} *M*) under nitrogen	5·8	3·7

Experimental conditions. (*A*) Porphyrin systems. 10 μmoles substrate, 1 ml. of 0·2 *M* phosphate buffer, *p*H 7·4, 60 μmoles semicarbazide and water to a final volume of 5 ml. were incubated in a Dubnoff metabolic shaker for 1 hr. at 37° C. under air. The hydrogen peroxide generating system consisted of 500 μmoles of glucose and 0·5 mgm. of glucose oxidase ('Notatin'). The reaction was terminated by addition of 15 ml. of 6·67 per cent trichloracetic acid. After removal of protein by centrifugation, aliquots of supernatant were assayed for formaldehyde by the chromotropic acid method of MacFadyen (ref. 3) as described in previous paper (ref. 1). (*B*) Ferric chloride system. 10 μmoles substrate and 30 μmoles of ferric chloride in 5 ml. of water were incubated for 0·5 hr. at 25° C. under nitrogen. Aliquots of reaction mixture were assayed directly for formaldehyde.

system it may be concluded that the systems functioned as peroxidases.

Hæmatin also catalysed the demethylation of the amines. It is of interest that the porphyrin could act both as a peroxidase and as an oxidase. For example, at low concentrations of hæmatin (about 2×10^{-5} *M*) hydrogen peroxide was required for appreciable activity. In contrast, at high concentrations (1×10^{-3} *M*) of hæmatin, dealkylation did not require hydrogen peroxide. Since no activity was observed anaerobically it was concluded that hæmatin at the higher concentration functioned as an oxidase.

The amines, with the exception of dimethylaniline, were also demethylated by inorganic iron when more than stoichiometric amounts of ferric chloride were used. Of particular note was the finding that this system was as active anaerobically as aerobically, showing that ferric ions served as electron acceptors in a dehydrogenase-like mechanism.

The effects of the various model systems on monomethyl-4-aminoantipyrine are summarized in Table 1. Results of a similar nature were obtained with the other amines. It is of interest that formaldehyde was also formed when 4-aminoantipyrine was the substrate, indicating that the dealkylation of monomethyl-4-aminoantipyrine and dimethyl-4-aminoantipyrine resulted in part from removal of the N-methyl group from the pyrazoline ring.

The results presented here indicate that iron-containing model systems can promote dealkylation by three types of oxidation :

(1) A peroxidase reaction :

$$R\text{—NH—CH}_3 + H_2O_2 \xrightarrow{\textit{peroxidase}} R\text{—NH—CH}_2\text{OH} + H_2O$$

$$R\text{—NH—CH}_2\text{OH} \longrightarrow R\text{—NH}_2 + \text{HCHO}$$

(2) An oxidase reaction :

$$R\text{—NH—CH}_3 + \tfrac{1}{2}O_2 \xrightarrow{\textit{hæmatin}} R\text{—NH—CH}_2\text{OH}$$

$$R\text{—NH—CH}_2\text{OH} \longrightarrow R\text{—NH}_2 + \text{HCHO}$$

(3) A dehydrogenation reaction :

$$R\text{—NH—CH}_3 + 2\text{Fe}^{3+} \rightarrow R\text{N=CH}_2 + 2\text{Fe}^{2+} + 2\text{H}^+$$

$$R\text{N=CH}_2 + \text{HOH} \longrightarrow R\text{—NH—CH}_2\text{OH}$$

$$R\text{—NH}-\text{CH}_2\text{OH} \longrightarrow R\text{—NH}_2 + \text{HCHO}$$

A hydroxymethyl intermediate has been postulated as an intermediate in the dealkylation of methylamines[4]. Our studies have provided evidence in favour of the formation of such an intermediate. When monomethyl-4-aminoantipyrine was incubated with the methæmoglobin system in the absence of semicarbazide, both formaldehyde and the primary amine were formed ; on the other hand, in the presence of semicarbazide only a trace of the primary amine appeared (Table 2). These results could be explained by postulating the formation of a hydroxymethyl derivative which is stable in the incubation mixture when semicarbazide is absent, but would yield 4-aminoantipyrine when the reaction is stopped by the addition of trichloracetic acid. In the presence of semicarbazide, however, the hydroxymethyl intermediate would react, as formed, to yield formaldehyde semicarbazone and 4-aminoantipyrine. But 4-aminoantipyrine as well as aniline has been found to be very unstable in the various peroxidase model systems whether or not semicarbazide was added. This would explain the failure to find the primary amine in the incubation system which contained semicarbazide, since removal of formaldehyde would expose the free amine to destruction by the peroxidase systems.

Table 2 EFFECT OF SEMICARBAZIDE ON ACCUMULATION OF 4-AMINOANTIPYRINE (AAP) FORMED FROM MONOMETHYL-4-AMINOANTIPYRINE

	AAP formed (μmoles)	Formaldehyde formed (μmoles).
Methæmoglobin ($1\cdot4 \times 10^{-5}$ *M*) plus

without semicarbazide	2·3*	2·8*
with semicarbazide	0·2	1·9

Incubation conditions: 10 μmoles substrate, 1 ml. of 0·2 *M* phosphate buffer, *p*H 7·4, the hydrogen peroxide generating system (500 μmoles glucose and 0·5 mgm. glucose oxidase) and water to a final volume of 5 ml. were incubated with and without 60 μmoles of semicarbazide for 1 hr. at 37° C. in an atmosphere of air. The reaction was terminated by addition of 15 ml. of 6·67 per cent trichloracetic acid. After removal of protein by centrifugation, aliquots of supernatant were assayed for 4-aminoantipyrine as described in a previous paper (ref. 1).

* Semicarbazide added at end of incubation period just before addition of acid.

Previous studies[5] have shown that hydroxylation of aromatic rings and cleavage of ethers can be brought about by a model system consisting of ascorbic acid, oxygen and inorganic iron chelated with ethylenediaminetetracetic acid. Evidence was adduced that the actual oxidant may be an unstable complex of hydrogen peroxide with the chelated iron. Since the methæmoglobin protein system also forms a hydrogen peroxide complex[6], it is possible that a hydrogen peroxide complex is also involved in the dealkylation of the alkylamines. Studies on the action of both types of model systems on other oxidative pathways of drug metabolism are being continued.

The material in this communication has appeared in a thesis by James V. Dingell in partial fulfilment of the requirements for the degree of master of science in the Department of Chemistry, Georgetown University, Washington, D.C.

Determination of Orbital Characteristics of an Earth Satellite from Single-Station Radio-Transit Observations

Meridian transit radio observations have been made of the Satellite 1958α by means of a modified Minitrack Mark II interferometer located at the Sohio Research Laboratories east of Cleveland, Ohio (lat. 41° 26·3′ N., long. 81° 32′ W.). Because of the generally low altitude of the satellite at this station, the horizontal dipoles were replaced with commercial Yagi antennas, following a suggestion of G. W. Swenson, jun., of the University of Illinois. The completed system acts as a compound interferometer in that two pairs of Yagis are separated by 2·5 wave-lengths from each other and 55 wave-lengths from the other two pairs. This was done to minimize lobe ambiguities. The antenna system deviates about 0·3 deg. from the true east–west base-line as determined by solar transit observations. The receiving system consists of a low-noise preamplifier, triple-conversion receiver, *WWV* time-marking circuit and a dual-channel recorder which was kindly loaned by the Brush Instrument Co. More than 120 transits have been observed to date. Fifty-six transits between Feb. 15 and Feb. 27 were selected for further analysis, as the multiple interferometer was in operation during that time.

The time between successive meridian passages (the synodic period) was found to give a considerable amount of information on the orbital characteristics of the satellite. In the interval between the sidereal and synodic periods the satellite covers about 30 deg. of arc in its orbit. The time to cover a given arc depends on the orbital angular velocity, which is a function of the period, eccentricity and true anomaly. The length of the arc depends on the time interval, the longitude of the node and the inclination. Values for the period, ρ ; R.A. of ascending node, Ω ; argument of perigee, ω ; eccentricity *e* and inclination *i* at epoch (Feb. 1, 0358 U.T.) were adopted from *Harvard Announcement Card* 1393. The inclination was afterwards found to require correction. The instantaneous values of ρ, Ω and ω at the time of observation depend on the time-rate of change of the period, the regression of the node and the advance of the line of apsides respectively. The 56 transits gave 43 observed values of the synodic period. These were compared with values of the corresponding synodic periods computed on an *IBM* 650 for various values of $\dot{\rho}$, $\dot{\Omega}$, $\dot{\omega}$ and *i*. The change in the eccentricity had a minor effect on the angular velocity in the time-interval considered, and a mean value was used.

The following values were adopted on the basis of minimizing the sums of squares of the residuals :

$$\dot{\rho} = -\,0{\cdot}0209 \pm 0{\cdot}0007 \text{ min./day}$$
$$\dot{\Omega} = -\,4{\cdot}242 \pm 0{\cdot}025 \text{ deg./day}$$
$$\dot{\omega} = +\,6{\cdot}255 \pm 0{\cdot}018 \text{ deg./day}$$
$$i = 32{\cdot}08 \pm 0{\cdot}18 \text{ deg.}$$
$$\sqrt{\sum_i \frac{(O-C)_i^2}{n}} = 0{\cdot}18 \text{ min.}$$

The 'errors' or lack of fit refer to the change in the parameter necessary to change $\Sigma(O-C)^2$ by 0·01 min.², while keeping the other three parameters constant. The rate of change in period implies that the lifetime of the satellite will be of the order of two years.

The observed and computed synodic periods are plotted against the mid-point in Eastern Standard Time (E.S.T.) of the observation in Fig. 1. As 23 periods are only slightly less than two days, observations separated by this interval may be closely compared. The major change in the orbit during that time is due to the regression of the node. This causes the synodic periods west of the north point of the orbit (earlier in the day) to become shorter because of the shortening length of arc in the orbit. Correspondingly, periods east of the north point will lengthen because of the increasing orbital length of arc. Periods near the north point will be changed only slightly. On Feb. 15, the north point crossed the meridian at about 1530 E.S.T., shifting to about 1130 E.S.T. by Feb. 27 due to the regression of the node. Clearly some systematic residuals remain ; a further analysis is planned to improve the parameters. The accuracy of the present results cannot compare with those determined from many Minitrack stations, at which direction cosines of the satellite itself are found. What is of interest is the information attainable from meridian observations at a single station.

A detailed account of the observations and interpretation will be published elsewhere. The project was under the direction of A. L. Jones. The design of the system and recording of the observations were due to R. W. Burhans, P. S. Fay, Warren Jackson and many others of the Sohio Research Staff. Interpretation of the data was carried out by Gordon Grant. David Frazier was in charge of the *IBM* 650

A. M. SCHWARTZ, J. W. PERRY and J. BERCH

1958 860 pages 26 illustrations 7 tables 132/-

This book supplements and extends the previous volume entitled *Surface Active Agents: Their Chemistry and Technology*. The two constitute a set, with volume 1 covering a field up to the beginning of 1947 and volume 2 devoted to developments during the period 1947–1956. During the past decade, progress has been particularly rapid in product formulation and in the scientific investigation of such important fundamentals as the physical chemistry of surfactant solutions and the mechanism of detergency. Although, relatively speaking, a smaller proportion of the total effort in this field has been directed to the synthesis of molecules having surfactant properties, nevertheless, recently developed new types, such as the synthetic polymeric surfactants, have already achieved considerable practical importance and widespread acceptance.

SURFACE ACTIVE AGENTS:

Their Chemistry and Technology, Volume I

By A. M. SCHWARTZ and J. W. PERRY

1949 590 pages 51 illustrations 4 tables 96/-

Reviews of Volume I

"The authors have assembled in a very satisfactory manner the present knowledge of surface-active agents, and, although this branch of chemistry is expanding rapidly, their book will be much appreciated by all workers in the field. . . . " *R. Matalon in NATURE.*

"Considering the magnitude of the task, the authors are to be congratulated on their achievement . . . " *A. E. Alexander in SCIENCE PROGRESS.*

"This book will be welcomed by the large number of scientists who use surface active agents in one way or another and the authors are to be congratulated on producing the first critical account of a subject whose literature consists mainly of patents. . . . " *Transactions of the Faraday Society.*

Mathematics

EGGLESTON, H. G. Problems in Euclidean Space: Application of Convexity. (The Adams Prize Essay of the University of Cambridge, 1955–56.) (International Series of Monographs on Pure and Applied Mathematics, Vol. 5.) 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. viii+165. (London and New York: Pergamon Press, 1957.) 40*s.* net.*

HILLE, Einer, and PHILLIPS, Ralph S. Functional Analysis and Semi-Groups. Revised edition. (American Mathematical Society Colloquium Publications, Vol. 31.) 10¼ in.×7 in. (26 cm.×18 cm.). Pp. xii+808. (Providence, R.I.: American Mathematical Society, 1957.) 13.80 dollars.*

KEMPTHORNE, Oscar. An Introduction to Genetic Statistics. (A Wiley Publication in Applied Statistics.) 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xvii+545. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 102*s.* net.*

LOTMAR, D. Perspektivische Verkürzungen im Raum, und quasiperspektivische Verkürzungen im Raum und Zeit: Versuch einer Auflösung des Paradoxen an den allein auf Raum und Zeit bezüglichen Aussagen der speziellen Relativitätstheorie. 9½ in.×6¾ in. (24 cm.×17 cm.). Pp. 109. (Zürich: Orell Füssli Verlag, 1958). 15.55 Swiss francs; 15 D.M.*

SCOTT, J. F. A History of Mathematics from Antiquity to the Beginning of the Nineteenth Century. 10 in.×7 in. (25·5 cm.×18 cm.). Pp. xii+266+6 plates. (London: Taylor and Francis, Ltd., 1958.) 63*s.* net.*

STOKER, J. J. Water Waves: The Mathematical Theory with Applications. (Pure and Applied Mathematics: a Series of Texts and Monographs, Vol. 4.) 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xxviii+567. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 12 dollars.*

TRICOMI, F. G. Integral Equations. (Pure and Applied Mathematics: a Series of Texts and Monographs, Vol. 5.) 9 in.×6 in. (23 cm.×15·5 cm.). Pp. viii+238. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 7 dollars.*

Physics

EDMONDS, A. R. Angular Momentum in Quantum Mechanics. (Investigations in Physics, Vol. 4.) 9½ in.×6¼ in. (24 cm.×16 cm.). Pp. viii+146. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1957.) 30*s.* net.*

FAIRES, R. A., and PARKS, B. H. Radioisotope Laboratory Techniques. (Newnes Practical Science Books.) 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xii+244+4 plates. (London: George Newnes, Ltd., 1958.) 25*s.* net.*

FLÜGGE, S. (herausgegeben von). Handbuch der Physik. Band 16: Elektrische Felder und Wellen. 10 in.×6¾ in. (25·5 cm.×17 cm.). Pp. vii+753. (Berlin: Springer-Verlag, 1958.) 158 D.M.*

FRISCH, C. R. (edited by). Progress in Nuclear Physics, Vol. 6. (Progress Series.) 10 in.×6¼ in. (25·5 cm.×16 cm.). Pp. vii+297. (London and New York: Pergamon Press, 1957.) 84*s.* net.*

KUZNETSOV, V. D. Surface Energy of Solids. (A translation from the Russian.) 8 in.×6½ in. (20 cm.×16·5 cm.). Pp. vii+283. (London: H.M. Stationery Office, 1957.) 8*s.* 6*d.* net.*

LANDSHOFF, Rolf K. M. (edited by). Magnetohydrodynamics: a Symposium. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. x+115. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1957.) 32*s.* net.*

LECK, J. H. Pressure Measurement in Vacuum Systems. (Physics in Industry.) 9½ in.×6 in. (24 cm.×15·5 cm.). Pp. 144. (London: Chapman and Hall, Ltd., 1957. Published on behalf of the Institute of Physics.) 30*s.**

LÜPFERT, Ewald Helmut. Licht, Materie, Weltall im einheitlichen Naturbild: Neue Einblicke in die Grundlagen der Physik und Astronomie. 11¾ in.×8¼ in. (30 cm.×21 cm.). Pp. 70. (Stuttgart: Borkenkopf-Verlag, 1958.) 4 D.M.*

MAGNETISM: Report of the Symposium on Magnetism held in May, 1954, under the joint auspices of the National Institute of Sciences of India and the Indian Association for the Cultivation of Science. 9½ in.×6½ in. (24 cm.×16·5 cm.). Pp. vi+232. (Calcutta: Indian Association for the Cultivation of Science, 1957.) Rs. 7; 15*s.*; 2 dollars.*

MARTON, L. (edited by). Advances in Electronics and Electron Physics, Vol. 9. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. x+347. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 9 dollars.*

MASSIGNON, Daniel. Mécanique Statistique des Fluides: Fluctuations et Propriétés Locales. (Travaux et Recherches Mathématiques.) 9¾ in.×6¼ in. (25 cm.×16 cm.). Pp. xiv+264. (Paris: Dunod, 1957.) 3,900 francs.*

SEITZ, Frederick, and TURNBULL, David (edited by). Solid State Physics: Advances in Research and Applications, Vol. 5. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xv+455. (New York: Academic Press, Inc., 1957.) 11 dollars.*

SERIES, G. W. The Spectrum of Atomic Hydrogen. (Oxford Library of the Physical Sciences.) 8½ in.×5½ in. (21·5 cm.×14 cm.). Pp. viii+88. (London: Oxford University Press, 1957.) 8*s.* 6*d.* net.*

WILSON, A. J. C., BAENZIGER, N. C., WYART, J., and ROBERTSON, J. Monteath (edited by). Structure Reports for 1951, Vol. 15. 9¾ in.×6½ in. (25 cm.×16·5 cm.). Pp. vii+588. (Utrecht: N.V.A. Oosthoek's Uitgevers Mij, 1957.) 110 Dutch florins; 210*s.*; 29 dollars.*

WRIGHT, W. D. The Measurement of Colour. Second edition. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. ix+263. (London: Hilger and Watts, Ltd., 1958.) 52*s.* net.*

Engineering

BEARD, R. B., and ROTHERHAM, A. C. Space Flight and Satellite Vehicles. 8¾ in.×5½ in. (22 cm.×14 cm.). Pp. viii+150+12 plates. (London: George Newnes, Ltd., 1957.) 15*s.* net.*

DEWITT, David, and ROSSOFF, Arthur L. Transistor Electronics. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xii+381. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 60*s.**

HUGHES, L. E. C. (edited by). Electronic Engineer's Reference Book. 7½ in.×5 in. (19 cm.×12·5 cm.). Pp. 1312. (London: Heywood and Company, Ltd., 1958.) 84*s.* net.*

KUETHE, A. M. (edited by). Proceedings of the Fifth Midwestern Conference on Fluid Mechanics held at the University of Michigan, April 1 and 2, 1957. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. viii+388. (Ann Arbor, Michigan: University of Michigan Press, 1957. Published for The Engineering Research Institute, Ann Arbor.) 8 dollars.*

KUETHE, A. M. (edited by). Proceedings of the Third Midwestern Conference on Solid Mechanics held at the University of Michigan, April 1 and 2, 1957. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. vi+250. (Ann Arbor, Michigan: University of Michigan Press, 1957. Published for The Engineering Research Institute, Ann Arbor.) 5.50 dollars.*

LEY, Willy. Rockets, Missiles, and Space Travel. Revised and enlarged edition. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xv+528. (London: Chapman and Hall, Ltd., 1957.) 50*s.* net.*

Chemistry : Chemical Industry

16TH INTERNATIONAL CONGRESS OF PURE AND APPLIED CHEMISTRY, Paris, 18–24 July, 1957: Main Lectures. (Experientia Supplementum, 7.) 9½ in.×6¾ in. (24 cm.× 17 cm.). Pp. 355. (Basel und Stuttgart: Birkhäuser Verlag, 1957.) 36 Swiss francs.*

BURR, Jr., John G. Tracer Applications for the Study of Organic Reactions. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. x+291. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 7.50 dollars.*

BUSVINE, J. R. A Critical Review of the Techniques for Testing Insecticides. 10¼ in.×7 in. (26 cm.×18 cm.). Pp. ix+208. (London: Commonwealth Institute of Entomology, 1957.) 30*s.**

CALDIN, E. F. An Introduction to Chemical Thermodynamics. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xv+424. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 50*s.* net.*

CREMER, Herbert W., and DAVIES, Trefor (edited by). Chemical Engineering Practice. Vol. 4: Fluid State. 10 in.×6½ in. (25·5 cm.×16·5 cm.). Pp. vi+623. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1957.) 95*s.*; 13.30 dollars.*

HABER, L. F. The Chemical Industry during the Nineteenth Century: a Study of the Economic Aspect of Applied Chemistry in Europe and North America. 9½ in.×6 in. (24 cm.×15·5 cm.). Pp. x+292. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 45*s.* net.*

HODGMAN, Charles D. (edited by). In association with WEAST, Robert C., and SELBY, Samuel M. Handbook of Chemistry and Physics: a Ready-Reference Book of Chemical and Physical Data. Thirty-ninth edition. 7½ in.×5 in. (19 cm.×12·5 cm.). Pp. xxii+3213. (Cleveland, Ohio: Chemical Rubber Publishing Company, 1957.) n.p.*

JACOB, A. Magnesium: The Fifth Major Plant Nutrient. Translated from the German by Dr. Norman Walker. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xii+159+8 plates. (London: Staples Press, Ltd., 1958.) 40*s.* net.*

KOLTHOFF, I. M., and BELCHER, R. With the co-operation of STENGER, V. A., and MATSUYAMA, G. Volumetric Analysis. Vol. 3: Titration Methods: Oxidation-Reduction Reactions. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. ix+714. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 15 dollars.*

SIMONSEN, Sir John, and ROSS, W. C. J. The Terpenes. Vol. 5: The Triterpenes and their Derivatives—Hydroxy Acids, Hydroxy Lactones, Hydroxyaldehydo Acids, Hydroxyketo Acids and the Stereochemistry of the Triterpenes. With Addenda to Volume 3 by Sir John Simonsen and Dr. P. de Mayo. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. ix+662. (Cambridge: At the University Press, 1957.) 84*s.* net.*

THOMSON, R. H. Naturally occurring Quinones. (Organic Chemistry Monographs.) 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. vii+302. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1957.) 50*s.*; 9 dollars.*

Technology

McCULLOUGH, C. Rogers (edited by). Safety Aspects of Nuclear Reactors. (The Geneva Series on the Peaceful Uses of Atomic Energy.) 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xii+237. (Princeton, N. J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1957.) 64*s.**

PEARSON, Eric B. Technology of Instrumentation. (Applied Physics Guides.) 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. 202. (London: English Universities Press, 1957.) 25*s.* net.*

ZIMMERMANN, Erich W. Conservation in the Production of Petroleum: a Study in Industrial Control. (Petroleum Monograph Series, Vol. 2.) 9½ in.×6¼ in. (24 cm.×16 cm.). Pp. xxii+417. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1957.) 48*s.* net.*

Meteorology : Geophysics

MISCELANEA GEOFISICA publicada pelo Servico Meteorologico de Angola em Commemoracao do X Aniversario do Servico Meteorologico Nacional. 10½ in.×8 in. (26 cm.×20·5 cm.). Pp. v+366. (Luanda: Servico Meteorologico Angola, 1956.) n.p.*

WEEKES, K. (edited by). Polar Atmosphere Symposium, Part 2: Ionospheric Section, Oslo, 2–8 July, 1956. (AGARDograph No. 29, Part 2.) 10 in.×6½ in. (25·5 cm.×16·5 cm.). Pp. xiii+212. (London and New York: Pergamon Press, 1957. Published for and on behalf of Advisory Group for Aeronautical Research and Development, North Atlantic Treaty Organization.) 60*s.* net.*

Biochemistry : Physiology

DEUEL, Jr., Harry J. The Lipids : Their Chemistry and Biochemistry. Vol. 3 : Biochemistry—Biosynthesis, Oxidation, Metabolism, and Nutritional Value. 9¼ in.×6¼ in. (23·5 cm.×16 cm.). Pp. xxxvi+1065. (New York : Interscience Publishers, Inc. ; London : Interscience Publishers, Ltd., 1957.) 25 dollars.*

GENEVOIS, Louis. Traité de Chimie Biologique. Tome Premier : Aminoacides—Protéines—Protéases—Nucléines—Porphyrines—Enzymes Respiratoires. (Collection Euclide : Introduction aux Études Scientifiques —Chimie.) 7¼ in.×5¼ in. (18·5 cm.×13 cm.). Pp. viii+325+2 planches. (Paris : Presses Universitaires de France, 1957.) 1,800 francs.*

GILBERT, Frank A. Mineral Nutrition and the Balance of Life. 9¼ in.×6¼ in. (23·5 cm.×16 cm.). Pp. xv+350+30 plates. (Norman, Okla. : University of Oklahoma Press, 1957.) 5.95 dollars.*

GREEN, Harold D. (edited by). Shock and Circulatory Homeostasis : Transactions of the Fifth Conference, November 30, December 1, and 2, 1955, Princeton, N.J. 9¼ in.×6¼ in. (23·5 cm.×16 cm.). Pp. 337. (New York : Josiah Macy, Jr. Foundation, 1957.) 4.75 dollars.*

LINDSTRÖM, B., and BROWN, R. (edited by). Cytochemical Methods with Quantitative Aims : Biophysical and Biochemical Approaches. (Proceedings of the Symposium held September 27–29, 1956, by the Institute for Medical Cell Research and Genetics, Karolinska Institutet, Stockholm, Sweden.) 9½ in.×6¾ in. (24 cm.×17 cm.) Pp. viii+296. (New York : Academic Press, Inc. ; London : Academic Books, Ltd., 1957.) 9.50 dollars.

McCOLLUM, Elmer Verner. A History of Nutrition : The Sequence of Ideas in Nutrition Investigations. Edited by H. Bentley Glass. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. x+451. (Boston, Mass. : Houghton Mifflin Company, 1957.) 6 dollars.*

MEHLER, Alan H. Introduction to Enzymology. 9¾ in.×6¼ in. (23·5 cm.×16 cm.). Pp. viii+425. (New York : Academic Press, Inc., 1957). 10.80 dollars.*

POLYAK, Stephen. The Vertebrate Visual System : Its Origin, Structure, and Function and Its Manifestations in Disease, with an Analysis of Its Role in the Life of Animals and in the Origin of Man. Preceded by a Historical Review of Investigations of the Eye, and of the Visual Pathways and Centres of the Brain. Edited by Heinrich Klüver. 10¾ in.×8 in. (27 cm.×20 cm.). Pp. xviii+1390. (Chicago, Ill. : University of Chicago Press ; London : Cambridge University Press, 1957.) £16 17*s*. 6*d*.*

SHOCK, Nathan W. A Classified Bibliography of Gerontology and Geriatrics, Supplement One, 1949–1955. 11 in.×8 in. (28 cm.×20 cm.). Pp. xxviii+525. (Stanford, Calif. : Stanford University Press, 1957.) 15 dollars.*

Anthropology : Archæology

BOULE, Marcellin, VALLOIS, Henri V. Fossil Men : a Textbook of Human Palaeontology. (Translated from the revised and enlarged Fifth French edition of "Les Hommes Fossiles", by Michael Bullock.) 9½ in.×6½ in. (24 cm.×16·5 cm.). Pp. xxv+535. (London : Thames and Hudson, Ltd., 1957.) 84*s*. net.*

CARSTAIRS, G. Morris. The Twice-Born : a Study of a Community of High Caste Hindus. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. 343. (London : The Hogarth Press, Ltd., 1957.) 30*s*. net.*

PIDDINGTON, Ralph. An Introduction to Social Anthropology, Vol. 2. 9 in.×6 in. (23 cm.×15·5 cm.). Pp. xvi+443–819. (Edinburgh and London : Oliver and Boyd, Ltd., 1957.) 30*s*. net.*

THE ANNUAL OF THE BRITISH SCHOOL AT ATHENS, No. 51, 1956. 10 in.×7½ in. (25·5 cm.×19 cm.). Pp. viii+176+43 plates. (London : The British School at Athens, 1958.) 63*s*. net.*

TURNER, V. W. Schism and Continuity in an African Society : a Study of Ndembu Village Life. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xxiii+348+7 plates. (Manchester : Manchester University Press, 1957. Published on behalf of the Rhodes-Livingstone Institute, Northern Rhodesia.) 35*s*. net.*

Philosophy : Psychology

BECKWITH, Burnham P. Religion, Philosophy, and Science : an Introduction to Logical Positivism. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xii+241. (New York : Philosophical Library, 1957.) 3.75 dollars.*

FINK, Eugen. Zur Ontologischen Frühgeschichte von Raum—Zeit—Bewegung. 9¾ in.×6¼ in. (25 cm.×16 cm.). Pp. xi+247. (The Hague : Martinus Nijhoff ; London : B. T. Batsford, Ltd., 1957.) 31*s*. 6*d*.*

KATTSOFF, Louis O. Physical Science and Physical Reality. 9¾ in.×6¼ in. (25 cm.×16 cm.). Pp. viii+311. (The Hague : Martinus Nijhoff ; London : B. T. Batsford, Ltd., 1957.) 36*s*.*

MUELLER-DEHAM, Albert. Human Relations and Power : Socio-Political Analysis and Synthesis. 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. xxi+410. (New York : Philosophical Library, 1957.) 3.75 dollars.*

SHEPHERD, Michael. A Study of the Major Psychoses in an English County. (Maudsley Monographs, No. 3.) 10 in.×6¼ in. (25·5 cm.×16 cm.). Pp. 159. (London : Chapman and Hall, Ltd., 1957.) 25*s*. net.*

Miscellany

ALLARDICE, Corbin (edited by). Atomic Power : An Appraisal including Atomic Energy in Economic Development. (International Series of Monographs on the Economic Aspects of Nuclear Energy, Vol. 1.) 8¾ in.×5¾ in. (22 cm.×15 cm.). Pp. 151. (London and New York : Pergamon Press, 1957.) 21*s*. net.*

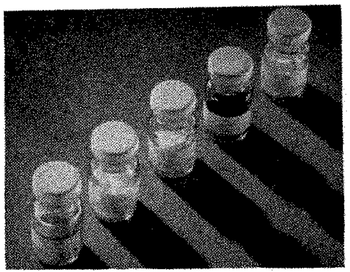
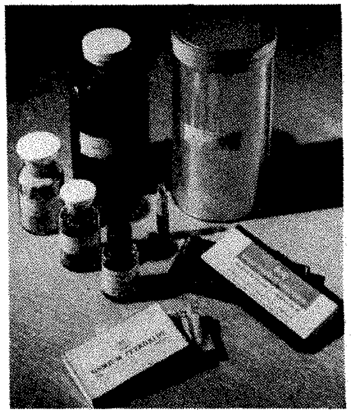
Compounds of the Minor and Rarer Metals



Rare Earths



Compounds of the Precious Metals

Chemical Products

From the earliest days of the company, the compounds of silver, gold and the platinum metals have been among Johnson Matthey products. More recently, the experience and manufacturing resources built up over the years have been turned to the preparation of other important compounds and there is available to-day a wide range of specialised inorganic chemicals of high purity—the simple and complex salts of the precious metals, compounds of the minor and rarer metals, and rare earths.

Johnson Matthey

Publication 1750, free on request, gives details of the chemical products in regular supply

Electron Micrographs of Monolayers of Stearic Acid

AT the second International Congress of Surface Activity held in London during April 1957, we presented results of a study with film balance and electron microscope of monolayers of *n*-hexatriacontanoic acid[1]. This compound shows small islands irregular in size and shape at low surface pressures (15 dynes/cm.), a continuous monolayer with discontinuous uncovered areas at intermediate pressures (25 dynes/cm.), a continuous homogeneous monolayer at high pressures (40 dynes/cm.), and long flat structures two molecules thick after collapse.

Monolayers of other compounds have since been examined: stearic, arachidic, *n*-hexacosanoic and *n*-dotetracontanoic acids give, as expected, monolayer structures much like those of *n*-hexatriacontanoic acid; *n*-octadecyl alcohol and cholesterol show related structures. Of principal interest is the behaviour of stearic acid at low surface pressures. It is the classical compound in monolayer research; but because of the small thickness of its monolayer it is more difficult to study in the electron microscope than *n*-hexatriacontanoic acid.

Monolayers of stearic acid were successfully transferred from the film balance at surface pressures as low[2] as 3 dynes per cm. An electron micrograph of such a sample is shown in Fig. 1. The direction of shadow-casting is indicated by an arrow; shadows appear as light areas. Many small islands, irregular in shape and about 1000 A. in diameter, are observed. Shadow widths establish that the islands are about 25 A. or one molecule thick. Close examination reveals that the spaces between islands actually contain many small structures. Presumably, smaller aggregates and individual molecules beyond the limit of the electron microscope may also be present.

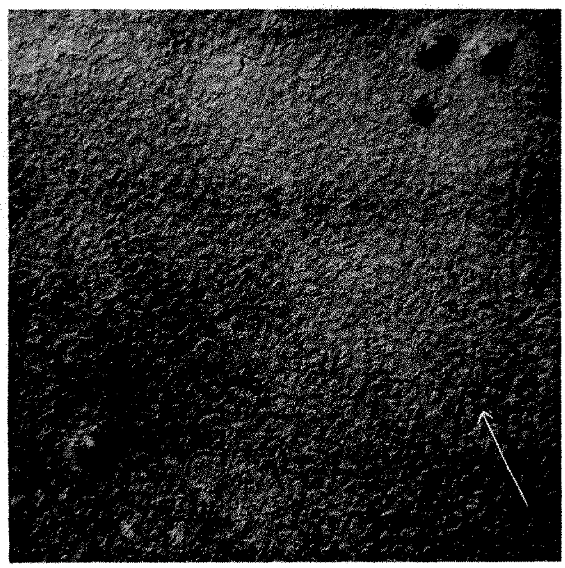

Fig. 1. Monolayer of stearic acid at 3 dynes per cm.

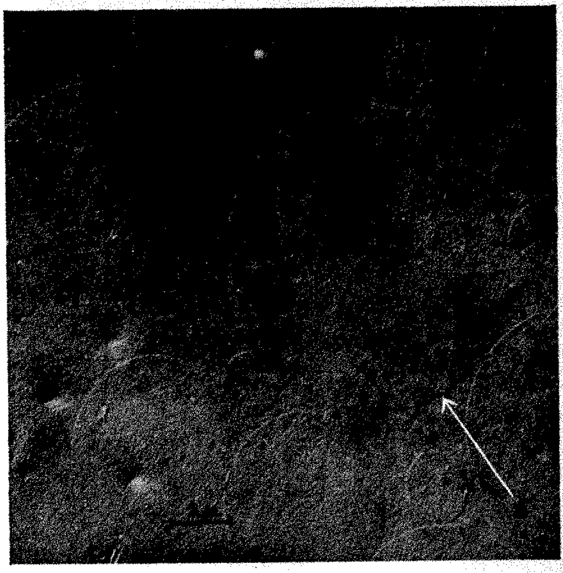

Fig. 2. Monolayer of stearic acid at 10 dynes per cm.

At greater surface pressures, less area remains uncovered. Fig. 2 is an unusual micrograph of a stearic acid monolayer transferred from the film balance at 10 dynes per cm. Most striking is the circular geometry of many of the islands, diameters of which range from 3000 to 50,000 A. In related monolayer studies, approximately circular islands, circular holes, and circular platelets on top of monolayers have been observed.

Circular islands that resemble flattened liquid droplets are somewhat surprising when one considers that the melting point of stearic acid is 69° C. and that the experiments were conducted at 25° C. However, forces at an edge of a 'two-dimensional' monolayer may be analogous to forces in the surface of a 'three-dimensional' system. Just as spheres with minimum surface energy appear in bulk liquid systems, circular disks may be expected in monolayers with sufficient mobility. Possible effects of droplets forming in the water film sandwiched temporarily between the monolayer and the collodion support used in transfer must also be considered; new transfer techniques now under study may resolve such effects. Experiments at higher temperatures should help define the role of surface mobility in the formation of monolayer islands.

Effect of Hydrogen on the Deformation Characteristics of Alpha-Titanium

It is well known that when iodide titanium containing more than 10 p.p.m. by weight of hydrogen is slowly cooled from 300° C. to room temperature, a second phase, titanium hydride, is precipitated in the alpha-titanium matrix.

X-ray and microscopical studies on single crystals have revealed that the precipitate is in the form of platelets, which lie mainly along the $\{10\bar{1}0\}$ slip planes. It is therefore natural to associate the precipitation with dislocations on the $\{10\bar{1}0\}$ system, especially as preferential precipitation occurs in regions of high plastic strain. If it is assumed that a $\{10\bar{1}0\}$ dislocation can dissociate as postulated by Churchman[1], the stacking fault structure associated with this dissociation requires only small additional movements of the titanium atoms to arrange these as the titanium atoms in either of the published structures for titanium hydride[2–5].

Evidence that hydrogen atoms do segregate around dislocations is provided by the observation of a very rapid strain ageing phenomenon in titanium during tensile experiments at 250° C. Calculations reveal that of the common impurities only hydrogen could diffuse at a fast enough rate to explain this effect. Experiments were carried out on both single crystals and polycrystalline titanium, which had previously been hydrogenated, the oxygen and nitrogen content being less than 0·01 weight per cent.

Little or no strain age-hardening was observed, and the work-hardening was of a parabolic nature with no significant increase in flow stress due to the presence of hydrogen. This differentiates the present deformation characteristics from those caused by 0·1 weight per cent oxygen plus nitrogen, where there is a very low linear rate of work hardening with an increased flow stress[6]. This difference suggests there is some fairly weak barrier to dislocation movement in titanium containing only low amounts of oxygen and nitrogen. Examination of the possible dislocations in the hexagonal lattice shows that two dissociated $\{10\bar{1}0\}$ dislocations on intersecting planes can combine to form a stable barrier of the Cottrell–Lomer type[7,8], which could hinder subsequent slip.

Embrittlement under impact-testing conditions occurs by the propagation of cracks which are associated with the hydride platelets. These cracks are caused by interference of the hydride phase with subsequent slip and twinning processes.

The above results will shortly be published in greater detail elsewhere.

I wish to thank Dr. A. T. Churchman for his encouragement and many valuable discussions.

Occurrence of Beryllium Oxide in Polycrystalline Beryllium

Sloman[1] has claimed to have found, using optical microscopy in conjunction with chemical analysis, that a beryllium oxide/beryllium eutectic forms at grain boundaries in vacuum-cast beryllium containing 0·3 per cent oxide by weight. By contrast, other workers[2] have since been unable to detect such oxide, either in the grain boundaries or present as inclusions in metal of comparable purity. It is still generally agreed, however, that the brittleness of beryllium is probably associated with some impurity, and our current results support the original claims by Sloman.

Our beryllium specimens were fabricated from electrolytic flake beryllium which had been vacuum-cast (~ 1,400° C.). The ingots were extruded at about 1,000° C. to form both rod and tube of about 1 in. diameter and by analysis were found to contain approximately 0·25 per cent beryllium oxide by weight. Our electron-diffraction study shows that specimens prepared from four different batches of such beryllium contain variable amounts of the oxide, which is probably concentrated at grain boundaries: it is clearly in the form of relatively large crystals (greater than 500 A. in diameter). It has been shown[3] that beryllium oxide is crystalline when formed or heated at temperatures above about 280° C., and develops as relatively large crystals (greater than about 500 A. in diameter) when the metal is heated in air above 600° C. for half an hour or more. The beryllium oxide in the present case must therefore have been formed at, or subjected to, temperatures in excess of 600° C., probably above 800° C., during the electrolytic preparation, vacuum casting or extrusion.

The beryllium oxide is distributed throughout the material, as the following example shows. A 1-in. rod was turned down to 1 cm. diameter, and flat surfaces of transverse and longitudinal sections were prepared by grinding, followed by abrasion on emery papers down to grade 0000, then on fine (3μ) diamond powder. The final distorted surface layer was removed by electropolishing[4], which further smoothed the surface and showed the grain size to be about 40μ. Etching the surface in 10 per cent aqueous sulphuric acid for 30 sec. dissolved the metal preferentially at about 100 A. thickness per sec., but a beryllium oxide surface produced by heating another such sample of the metal in air (for example, at 400° C. for half an hour) was passive in the solution. Fig. 1, obtained by electron diffraction after etching the metal, shows arcs due to the beryllium (which we found has a

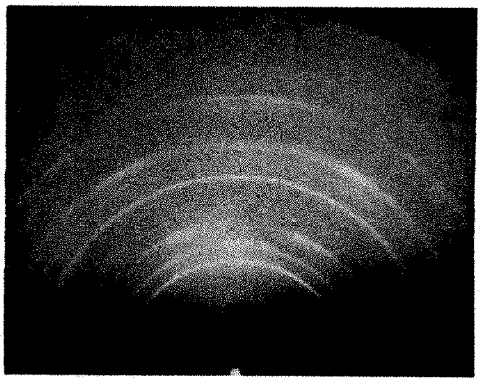

Fig. 1

pronounced <210> fibre texture with the orientation axis parallel to the rod axis), and in addition strong sharp rings indicating randomly orientated beryllium oxide crystals of at least 500 A. in diameter. Such oxide was found repeatedly after re-surfacing in the manner described.

When preparing single-crystal surfaces in this way, clear Kikuchi-line and spot patterns were obtained with no sign of sharp diffractions from oxide. Thus the oxide observed on the polycrystalline surface was not produced as a result of the method of surfacing. Clearly, therefore, in the case of the hot-extruded material described above, the preferential solution of the beryllium by the etchant must have left the oxide crystals projecting above the metal, thus increasing their relative contribution to the diffraction pattern.

Further investigations, particularly of the penetration of oxygen into beryllium at high temperatures and the existence of oxide films in coarse and fine-grain vacuum-cast metal, are in progress.

We wish to thank Mr. G. C. Ellis and Dr. A. Moore for the provision of specimens and for helpful discussions. One of us (V. D. Scott) is on detached duty from the Atomic Weapons Research Establishment, Aldermaston; we are indebted to the Director of this Establishment for permission to publish these results.

Kinetics of the Trigonal-to-Cubic Transition in Crystals of Cæsium Nitrate on Muscovite

It is well known[1] that the epitaxial orientation of cubic cæsium nitrate on muscovite is

$$\text{CsNO}_3\ (100)\ [010] = \text{muscovite}\ (001)\ [010]$$

whereas the orientation of trigonal cæsium nitrate is

$$\text{CsNO}_3\ (11\bar{2}1)\ [10\bar{1}0] = \text{muscovite}\ (001)\ [010],\ [130]\ \text{and}\ [1\bar{3}0]$$

From a general point of view, the possibility of obtaining definite orientations on definite crystallographic planes means that, of the many possible arrangements, there are some for which nucleation is more probable. In the language of statistical thermodynamics, this probability is $p = \exp\left(-\frac{\Delta F}{kT}\right)$. Consequently nucleation which gives rise to epitaxial crystals corresponds to a value of ΔF less than that for other possible arrangements. The interface between epitaxial crystals and the substrate crystal presents a smaller discontinuity than any other possible arrangement. In other words, this smaller discontinuity corresponds to both a smaller interfacial free energy and a smaller elastic strain energy.

Any polymorphic transformation undergone by the oriented crystals will involve an increase in this free energy. A shift of the equilibrium temperature, with respect to that of non-epitaxial crystals, may be foreseen. If the transformation takes place between phases of which only one is epitaxial, the shift will be large. If both phases are epitaxial, the shift will be in general smaller, and its direction will indicate the more stable epitaxy.

We have made simultaneous observations of the kinetics of the polymorphic transformation of cæsium nitrate from trigonal to cubic, on crystals of the same size obtained by evaporation of the same solution, (i) on a glass substrate and (ii) on a crystalline substrate (muscovite), in order to correlate the two processes. The two supports were placed in a Weigand heating apparatus[2] fitted to a Leitz microscope, so that the crystals oriented on the mica and the non-oriented crystals on the glass were in view simultaneously. The temperature of transformation was clearly defined by the disappearance (or appearance) of birefringence on heating (or cooling) uniformly (2 deg. C. per min. at first). We have established, in many experiments, that on heating, the birefringence appears first in the crystals on the glass substrate, and on cooling it appears later. The interval between the appearance of the birefringence in the two cases has never been more than 45 sec.

The difference in behaviour described above is quite small in comparison with that observed in other experiments. For example, for the transformation $\text{NaBr} \rightarrow \text{NaBr.2H}_2\text{O}$, in which only one phase (NaBr) is epitaxial on galena, the time difference with respect to sodium bromide unoriented on glass is almost two hours. In this case the hydration brings about an appreciable increase of the interfacial discontinuity. In the case of cæsium nitrate, however, the interfacial discontinuity varies little from one phase to the other. The direction of the variation indicates that the epitaxy of the trigonal phase is more stable and more probable.

We have recently shown[3] that the preponderant factor in determining the interfacial discontinuity is the amount of difference in symmetry. For cæsium nitrate, the change in the dissymmetry is almost negligible and shift in equilibrium is minimal.

An Electronic Mechanism of Addition Reactions

A recent communication from Mr. Lakhbir Singh[1] seems to require a reply based rather more firmly on conventional theoretical chemistry. He refers to the decrease in reactivity of acetylene compared to ethylene, and implies that this shows that an increase in the number of π-bonds leads consequently to a decrease in reactivity. Duchesne[2] has, however, pointed out that the greater reactivity of ethylene compared to acetylene is due to the fact that the torsional oscillations in ethylene uncouple the π-electrons, whereas this cannot happen in acetylene. Singh also describes allene as "very much strained". It is difficult to see why this should be so, unless reliance is placed on the Baeyer[3] strain theory. In modern terms the central atom may be described as having two σ-bonds in an *sp*-hybrid, with two *p*-orbitals available to form two π-bonds, the planes of which are at right-angles to each other. The low reactivity in cumulenes compared to polyenes can be attributed to the small effect of torsional oscillations on the environment of the central atoms.

Mr. Lakhbir Singh's arguments concerning the effect of electron-attracting and repelling groups can easily be replaced by the usual arguments involving hyperconjugation, and there is no need to postulate that the σ-electrons are all-important. If in addition reactions the attack is on the σ-electrons, it is difficult to see why there is any difference in reactivity between unsaturated and saturated compounds. In these and in benzene derivatives, Mr. Lakhbir Singh does not apparently distinguish between inductive and electromeric effects.

In his explanation, Mr. Lakhbir Singh apparently ignores the fundamental principle that the total electronic wave function must have the symmetry of the nuclear framework. His *p*-orbitals inclined at an angle are certainly not in accordance with this principle. He also suggests that "the distortion of the σ-electron orbits would be unsteady and non-uniform". This view seems to ignore the principle of stationary states.

It may well be, as he remarks, that the "quantum mechanical approach has not succeeded in solving this problem", but any explanation must not be contrary to the fundamental principles of quantum mechanics.

The Pigment of *Micrococcus lysodeikticus*

While culturing cells of *Micrococcus lysodeikticus*[1], white cells, resistant to lysozyme, were often produced in liquid media containing relatively high carbohydrate. Resistant cells remained Gram-positive and were not lysed by lysozyme in the presence of ethylenediaminetetraacetic acid[2]. Optimal concentrations of cultural sodium chloride for growth improved the yellow colour of the organisms[3]. These observations suggested a relationship of the yellow pigment to the polysaccharide substrate of lysozyme.

Extraction of the pigment directly from dried organisms[1] with petroleum ether (b.p. 40–60° C.) provided a lipid extract and poor pigment yield. The pigment failed to migrate on MgO–'Celite' (1 : 1) and disappeared rapidly from this adsorbent. The following method, however, gave good quantities of pigment. *M. lysodeikticus* was grown at 28° C. in 250-ml. shake flasks, each containing 100 ml. medium[3]. After 48 hr., cells were centrifuged and washed with 0·85 per cent saline. The equivalent of 4·2 gm. cell dry weight was used in a typical experiment. Cells were suspended in 50 ml. 0·85 per cent saline and 150 ml. *M*/15 phosphate buffer, *p*H 6·3. 40 mgm. Armour egg white lysozyme were added and lysis was carried out for 1 hr. with occasional shaking; 400 ml. cold acetone were added. Extraction was continued for 48 hr. (5° C.) with frequent shaking. The clear yellow supernatant was decanted and filtered by gravity (Whatman No. 1). Extraction was repeated with acetone. The second extract was more highly coloured. This was combined with the first fraction and evaporated to dryness in a stream of air at 25° C. The residue was extracted with 100 ml. petroleum ether, concentrated to 3 ml. (25° C.) and transferred to a 1 cm. × 12 cm. activated calcium carbonate column. (The non-extractable residue contained a yellow-orange pigment which was also insoluble in carbon disulphide but soluble in water. This has not been studied further.) The eluant was petroleum ether. Two yellow bands migrated on the calcium carbonate column[4], a fast-moving component, *A* (distribution coef. is about 1·9) and a low-moving component, *B* (distribution coef. is about 2·7). The distribution coefficient was calculated as K = vol. of eluant flowed into column ÷ fraction of column-length migrated by the band × gm. of adsorbent. Band *A* was eluted with petroleum ether. Band *B* was obtained by extruding the column and extracting the yellow segment overnight with absolute ethanol at 5° C.

Table 1. Visible Spectra of Fractions *A* and *B* in Various Organic Solvents

Fraction	Solvent	$E_{\text{max.}}$ (mμ)			
A	Petroleum ether (b.p., 40–60° C.)	468	440	414	(329)
B	,,	470	440	410	
A	Carbon disulphide	494	462	440	375
B	,,	490	460	378	
A	Calcium carbonate	477	447	423	
B	,,	470–80	440–50		

Characteristic $E_{\text{max.}}$ for the carotenoids are shown in Table 1. Although we have not seen reports concerning the pigments of *M. lysodeikticus*, Sobin and Stahly[4] have isolated carotenoids from several other species. Those species which have two yellow carotenoid alcohols similar to the pigments from *M. lysodeikticus* are *Sarcina lutea* and *M. flavus*. These pigments are dissimilar from a carotenoid from *M. aquivivus*, *M. maripuniceus* and *M. infimus*[5].

This investigation was supported in part by a Research Grant (*E*–1119 *C*), National Institute of Allergy and Infectious Diseases, National Institutes of Health, Public Health Service.

Bacterial Oxidation of Lactose and Melibiose

During an investigation of bacteria isolated from blocks of whale meat, two distinct strains of paracolon bacteria (*B*1*x*, urease-positive; and *C*6, urease-negative) were obtained, the sugar metabolism of which was interesting. Tested in the normal way with Durham tubes, these organisms produced acid from lactose within 5–12 days at 30° C. and were accordingly recorded as late lactose fermenters. Tested by Hugh and Leifson's[1] method, both strains fermented cellobiose, maltose, sucrose, trehalose, galactose, glucose, mannitol and sorbitol, producing acid and gas anaerobically within 48 hr. at 30° C.

Lactose, melibiose and glycerol, however, were not fermented but oxidized, that is, acid was produced from these sugars within 48 hr. under aerobic conditions only.

In shaken, aerobic cultures at 30° C. of strain *B*1*x*, containing 2 per cent (w/v) of lactose or melibiose, all reducing power disappeared within 48 hr. Paper chromatograms of culture filtrates, using *n*-propanol/ammonia (70 : 30) as solvent and sprayed with ammoniacal silver nitrate or thymol blue, showed respectively spots corresponding to lactobionic acid and melibionic acid (prepared by the method of Levene and Jorpes[2]), which were absent from control cultures without sugar. Comparison of the sizes of the spots with those of known concentrations of the acids suggested that the conversion of sugar to acid had, in each case, been nearly quantitative.

Confirmatory evidence of the identity of the acids was obtained by subjecting the filtrates, after passage over 'Zeo-Karb 225', to hydrolysis with *N* hydrochloric acid at 100° C. for 2 hr., removing the acid with silver oxide and running the resultant solutions on paper using the same solvent. On spraying with ammoniacal silver nitrate, spots corresponding to galactose and gluconic acid, absent from the original filtrates, were obtained. The acids present in the original culture filtrates have therefore been provisionally identified as lactobionic and melibionic.

It seems that this paracolon strain is able to oxidize lactose and melibiose to lactobionic and melibionic acids respectively. The oxidation of lactose by paracolon bacteria[1], and the oxidation of lactose and maltose to the corresponding acids by oxidative *Pseudomonas*[3,4] and *Achromobacter*[5] spp. have been reported, but so far as is known, this is the first recorded instance of the production of melibionic acid from melibiose. The wider use of the Hugh and Leifson technique would probably reveal more cases of this kind. This work emphasizes the inadequacy of the traditional fermentation tube technique in which both aerobic and anaerobic conditions exist.

I wish to thank Dr. F. A. Isherwood and Mr. F. C. Barrett for their help and advice.

Role of Oxygen in the Formation of α-Amino-butyric Acid by a Staphylococcus

The formation of α-amino-butyric acid by animal cells has been studied[1,2], but little is known of the method of its formation by staphylococci[3].

It has been shown here, using shaken flasks, that the formation of α-amino-butyric acid by staphylococci is a function of the amount of oxygen available to the culture. It has been confirmed that the acid can be derived from threonine and it has been shown that, presumably by a similar process, alanine can be formed from serine.

The organism used was the *V*8 strain of staphylococcus employed by Gladstone and van Heyningen[4]. The culture medium, consisting of 'Bacto Casamino-acids', 2 per cent; yeast diffusate, 20 per cent; sodium lactate, 0·75 per cent; sodium glycerophosphate, 2 per cent; and mineral salts was the same as that used by Gladstone and van Heyningen. The organisms were grown at 37° C. in 500-ml. conical flasks plugged with cotton wool, the oxygen solution-rate being varied by varying the volume of medium in the flask. When shaken on the bottom shelf of a Kantorowicz[5] shaker the flask containing 1/5 its volume of liquid gave an oxygen solution-rate determined by sulphite oxidation[6] of 29 m.moles O_2/l./hr. and the flask containing 1/20 its volume of liquid gave a value of 75 m.moles O_2/l./hr.

Changes in amino-acid composition of the medium during growth were followed by two-way chromatography.

While no new amino-acids appeared during growth in the flasks containing 1/20 their volume of medium, a fresh acid appeared early in the logarithmic growth-phase in the flasks containing 1/5 their volume of medium. This was shown to be α-amino-butyric acid.

Cells from flasks with the lower oxygen solution-rate incubated with threonine formed α-amino-butyric acid; with serine, alanine was formed, while with aspartic acid, glutamic acid or methionine, no new material appeared. Cells from flasks with the higher oxygen solution-rate similarly treated produced no changes.

When nitrogen was substituted for air in sealed flasks with 1/20 vol. medium, α-amino-butyric acid was formed during growth. When both sodium lactate and sodium glycerophosphate were omitted from the medium, the staphylococci still grew well. It was shown that growth in such a medium in the flasks containing 1/5 vol. medium failed to produce α-amino-butyric acid, whereas with lactate and glycerophosphate present it was formed. Replacement of air by nitrogen when lactate and glycerophosphate were absent from the flasks containing 1/5 vol. medium brought about formation of α-amino-butyric acid.

When glucose or glycerol was substituted for lactate and glycerophosphate on an equimolar basis, α-amino-butyric acid was still formed during growth in flasks containing 1/5 vol. medium. The use of pyruvic acid, malic acid, formic acid, succinic acid or α-keto-glutaric acid as a substitute for lactate and glycerophosphate failed to bring about α-amino-butyric acid formation. Addition of pyruvic acid to the lactate-containing medium in the flasks with the lower oxygen solution-rates suppressed the formation of α-amino-butyric acid.

It would seem from these results that the formation of α-amino-butyric acid by this staphylococcus is due to the use of threonine as a hydrogen acceptor under conditions of low oxygen supply, serine presumably functioning in a similar manner.

An Alternative Pathway for the Degradation of Cholic Acid by Micro-organisms

Since the publication of the first report[1] on the microbiological degradation of cholic acid (I) to 7α-hydroxy-3 : 12-dioxo-Δ^4-*bis*-norcholenic acid (VII) by *Streptomyces gelaticus* 1164, additional investigations have been continued and two possible pathways[2] for cholic acid degradation have been proposed.

S. gelaticus 1164 can grow on a medium containing the *bis*-nor acid (VII) as the sole source of carbon. On the other hand, *Streptomyces rubescens*[3] is able to utilize cholic acid as the sole source of carbon as well as *S. gelaticus* 1164, but is unable to utilize this *bis*-nor acid.

Though interpretation of such experiments is not simple, we suggest that cholic acid degradation by *S. rubescens* proceeds through an alternative pathway different from that found with *S. gelaticus* 1164.

Recently, it was found[4] that *S. rubescens*, cultured in a medium containing cholic acid as the sole source of carbon, produced various intermediates such as 7α : 12α-dihydroxy-3-oxo-Δ^4-cholenic acid (III), 7α-hydroxy-3 : 12-dioxo-Δ^4-cholenic acid (IV), 12α-hydroxy-3-oxo-$\Delta^{4,6}$-choladienic acid (V), 3 : 12-dioxo-$\Delta^{4,6}$-choladienic acid (VI) and some unidentified compounds different from the *bis*-nor acid (VII).

Considering the structures of these intermediates, an oxidative pathway of cholic acid by *S. rubescens* may be deduced as follows (Fig. 1), though the acid II has not yet been isolated.

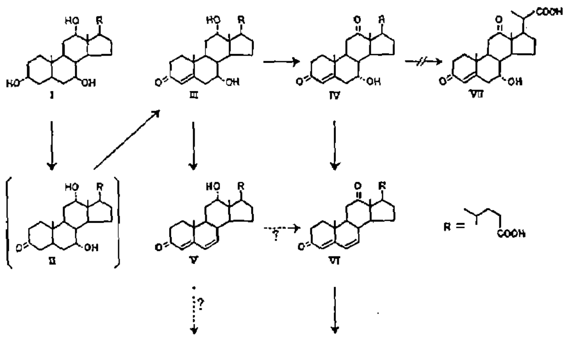

Fig. 1

S. rubescens cultures in a cholate medium give a light absorption peak at 246 mμ at the earlier incubation period, and a parallelism between an increase of the optical density and the incubation period is observed. After the optical density at 246 mμ reaches its maximum, it decreases in parallel with continuation of the incubation, and, simultaneously, a new peak at 290 mμ appears ; finally, both the peaks at 246 and 290 mμ disappear at an almost equal rate at the end of the incubation period.

These findings may be interpreted as follows : an appearance of a peak at 246 mμ in the cholate culture begins with the conversions $\mathrm{I} \rightarrow \mathrm{II} \rightarrow \mathrm{III} \rightarrow \mathrm{IV}$; a decrease of the optical density at 246 mμ and an appearance of a peak at 290 mμ are due to the conversion $\mathrm{III} \rightarrow \mathrm{V}$ or $\mathrm{IV} \rightarrow \mathrm{VI}$; and further degradation of V or VI accelerates the conversion $\mathrm{III} \rightarrow \mathrm{V}$ or $\mathrm{IV} \rightarrow \mathrm{VI}$. This process will finally lead to the disappearance of both the peaks at 246 and 290 mμ.

Much of the representation of our proposed pathway for cholic acid degradation by *S. rubescens* is still largely hypothetical. However, the isolation and identification of the acids V and VI in this experiment demonstrate for the first time a microbiological introduction of the $\Delta^{4,6}$-3-ketone structure into the cholane nucleus of cholic acid.

Further study on the proposed pathway is in progress and will be reported in detail elsewhere.

Uridine Diphosphate Amino-sugar Compounds from *Staphylococcus aureus* inhibited by Penicillin

In 1952, Park[1] showed that three uridine diphosphate amino-sugar compounds were accumulated in *Staphylococcus aureus* inhibited by penicillin. Compound I contained no amino-acid residue. Compound II contained one alanine residue and compound III contained a peptide which was composed of one glutamic acid, one lysine and three alanine residues. Recently, Strominger indicated that, even though in much smaller amount, these compounds are contained also in normal cells[2], and that the amino-sugar component is 3-O-carboxyethyl glucosamine[3], which is known as one of the main components of cell walls[4].

We have found a variety of similar uridine diphosphate amino-sugar compounds, some of which contained aspartic acid and glycine. Cells of *S. aureus* strain 209 *P* treated with penicillin were extracted with trichloracetic acid. After removal of trichloracetic acid, barium hydroxide and sufficient sodium hydroxide were added to the extract to adjust the *p*H to 9, and the precipitate was removed. To the concentrated supernatant, ethanol was added to 50 per cent by volume and the precipitate was separated. More ethanol was added to the supernatant to make it 90 per cent and the precipitate was separated. Each precipitate was fractionated by ion exchange chromatography with 'Dowex 1' in the chloride form. The fractions with the same peak of optical density at 260 mμ were pooled, concentrated by adsorption on 'Norit' and subsequent elution with ammoniacal ethanol, and were analysed for components. After hydrolysis with 6 *N* hydrochloric acid at 120° for 6 hr. in a sealed tube, amino-acids were separated and estimated by two-dimensional paper chromatography with butanol/acetic acid/water (4 : 1 : 5) and phenol/*m*-cresol/borate buffer *p*H 9·3 (25 : 25 : 7) as solvent systems[6]. The result of paper chromatography on fractions containing appreciable amounts of all the three components, uridine, N-acetyl-amino-sugar and amino-

acids, is shown in Table 1; the amounts of samples were adjusted to give about the same amino-sugar content. When normal cells were treated similarly, much smaller amounts of amino-acid-containing uridine derivatives were obtained, in which the same species of amino-acid residues were detected as in the case of the penicillin-treated cells.

The result suggests that there may be a number of compounds containing some of the five amino-acids in various combinations. Further attempts to separate each fraction into components are in progress. In connexion with the present results, it is to be noted that alanine, lysine and glutamic acid have been found in cell walls of Gram-positive micro-organisms as the main components[3,4,6], whereas glycine has been discovered in cell walls of *Staphylococci*[4] and aspartic acid in cell walls of *Lactobacilli*[4]. This is additional evidence for Strominger's hypothesis[3] that these uridine diphosphate amino-sugar compounds are possible precursors of cell walls.

Further details of this work will be reported elsewhere.

An Antibiotic produced by a *Bacillus* sp., active against *Haemophilus pertussis*

A STRAIN of *Bacillus* (probably *B. subtilis*) has been found to produce an antibiotic effective against *H. pertussis* and *Neisseria* spp. The antibiotic spectrum is somewhat unusual, and although attempts at purification achieved little, the following is a summary of the results[1].

The antibiotic is produced in highest concentration (titre 1 in 128 against *N. meningitidis*) in aerated culture at 22° in a medium containing horse-meat and potato extracts. Growth in a synthetic medium based on that of Hills *et al.*[2] yielded an antibiotic of different properties; this material was not further investigated. The antibiotic was extracted from the enriched medium by extraction with *n*-butanol at *p*H 4·5. Removal of the butanol and extraction with *n*-hexane yielded an amorphous brown powder (petrin) containing most of the activity (titre 1 in 125,000 against *N. meningitidis*).

Extraction of petrin with a number of organic solvents yielded several fractions, all with the same activity, and with the same composition as determined chromatographically.

Paper chromatography of petrin, using a chloroform/*n*-butanol/water (46 : 4 : 50) solvent mixture, indicated the presence of at least three fractions: (*a*) antibiotic, (*b*) hæmolytic, (*c*) fluorescent in ultra-violet light. Active material could not readily be extracted from the paper.

Emulsion formation precluded the use of a Craig countercurrent extraction apparatus, but by repeated centrifugation a ten-tube distribution was accomplished. The principal antibiotic-containing fraction did not contain nitrogen. A smaller antibiotic-containing fraction did contain nitrogen.

The *LD*50 for 20-gm. mice injected intraperitoneally was 5 mgm.

A summary of the antibiotic spectrum of petrin is given in Table 1.

Table 1. ANTIBIOTIC SPECTRUM OF PETRIN

Organism	Dilution of antibiotic	
	growth at	inhibition at
N. meningitidis	150,000	125,000
N. gonorrhoeae	75,000	50,000
N. catarrhalis	5,000	1,000
H. pertussis	125,000	100,000
H. influenzae	50,000	25,000
H. parapertussis	100,000	50,000
C. diphtheriae	25,000	5,000

No inhibition at 1/200 of *E. coli*, *A. aerogenes*, *Sh. sonnei*, *Sh. flexneri*, *Salm. typhi*, *Ps. pyocyanea*, *Prot. vulgaris*, *Kleb. pneumoniae*, *Staph. albus*, *Staph. aureus*, *Clostridium* spp., *Candida albicans*, *Aspergillus niger*, *Penicillium notatum*.

The physical and chemical properties of petrin are: soluble in water above *p*H 4·5; stable at room temperature in the range *p*H 4·5–11; boiling at *p*H 8·0 reduced the activity by 66 per cent in 10 min., thereafter it remained constant for 50 min.; stable to pepsin and trypsin; stable to dry heat (100°); adsorbed on to charcoal but not readily eluted; partially soluble in chloroform, ethanol; insoluble in acetone, ether.

Comparison of petrin with 26 other antibiotics attributed to *B. subtilis*, and 29 antibiotics attributed to other members of the Bacillaceae, indicated that petrin has not previously been described.

My thanks are due to Prof. J. W. McLeod and Prof. C. L. Oakley for their interest and encouragement.

Flavofungin, a New Crystalline Antifungal Antibiotic: Origin and Biological Properties

DURING the systematic study of actinomycetes antagonizing fungi pathogenic in man, a species of *Streptomyces* (*SA*-IX/1) was found from desert sand that markedly inhibits growth of *Cryptococcus neoformans* and *Trichophyton mentagrophytes* used for screening[1]. In laboratory deep fermentation, besides the antifungal antibiotic, an antibacterial one was produced also by this species. A natural stable variant (*SA*-IX/3) differing morphologically from the original strain isolated was selected that is capable of producing increased quantities of the antifungal and decreased quantities of the antibacterial agent. This proved to be a new species and has been named *Streptomyces flavofungini*. The antifungal, crystalline antibiotic (Fig. 1) was isolated as a uniform product from the mycelium and fermentation fluid of this asporogenic, chromogenic variant. From its colour and effects, the new antifungal agent has been called 'flavofungin'.

Pure flavofungin has no influence upon growth of *Streptomycetes* and common bacteria; but the growth of *B. subtilis* and of a few strains of *M. pyogenes* var. *aureus* is inhibited by relatively high concentrations of more than 100 μgm./ml. Marked inhibition is exerted *in vitro* upon the growth of pathogenic and non-pathogenic yeasts and yeast-like fungi, dermatophytes, and also of saprophytic and plant pathogenic fungi; inhibitory concentrations are shown in Table 1. Assays were carried out by serial dilutions in Czapek–Dox, Sabouraud, Jensen and mush media. Its diffusion into agar is rather slow.

In aqueous suspension, given *per os* or subcutaneously, in dosages up to 250 mgm./kgm., to the mouse, no acute or late symptoms were evoked; *LD*50 is 25 mgm./kgm. in aqueous suspension given by the intraperitoneal route.

In the fæces of mice fed with *Candida albicans*, no colonies, or only a few, can be demonstrated after having received flavofungin *per os*, in marked contrast to untreated controls.

Flavofungin is strongly bound to serum proteins, but can be liberated.

According to its chemical, physical and biological properties, flavofungin is not identical with formerly known antifungal antibiotics[2]. Its isolation and chemical properties will be described in detail elsewhere.

Effect of Heparin on Pathologically Decreased Serum Esterase in Carcinoma

PLASMA and serum esterolytic activity may be considerably decreased in pathological conditions. The substrates most often used for the determination of esterolytic activity are acetylcholine[1], tributyrine[2] and procaine[3]. Decreased activity is found most often in cirrhosis of the liver and carcinoma. In our work ethyl butyrate was used as the substrate and esterase activity was determined by the titrimetric method[4]. The values are given in ml. of 0·05 *N* sodium hydroxide required to neutralize the acid liberated in 24 hr. In agreement with other workers we found low values, especially in some forms of carcinoma and cirrhosis. These low values are in sharp contrast to the increase in esterase activity

Table 1. Effect of Heparin on the Esterase Activity of Serum in Carcinoma

Case No.	Diagnosis	Esterase activity (ml. 0·05 *N* sodium hydroxide)	Rise of esterase activity after heparin injection (per cent)
1	Bronchiogenic carcinoma	0·42	780
2	Carcinoma of the stomach	0·44	259
3	Carcinoma of the stomach	0·78	203
4	Adenocarcinoma of the kidney	1·40	113
5	Bronchiogenic carcinoma	1·46	95
6	Bronchiogenic carcinoma	2·08	93
7	Bronchiogenic carcinoma	1·66	81
	Average in 25 controls	3·16	35

after administration of heparin. Five minutes after intravenous injection of heparin in amounts of 100 units per kgm. body-weight, the increase reached as much as 780 per cent (Table 1).

This increase is much greater than in normal persons, in whom esterase activity has an average value of 3·16 ml. 0·05 *N* sodium hydroxide[5] with a dispersion of 2·00–4·85, by our method. There is a definite increase after administration of heparin in normal persons[6], but it rarely exceeds 70 per cent and we found no increase greater than 100 per cent.

No explanation can at present be given for the great increase of the pathologically low values of esterase in carcinoma. There are, however, the following possibilities: (1) that there is an esterase inhibitor in the blood of the patients which is inactivated by heparin; (2) that heparin washes out from the tissues into the blood stream an esterase which, in carcinoma, is not, or is only partly, damaged and which is able to break down ethyl butyrate.

Effect of a Lethal Electric Shock during Hypothermia

In our experiments we applied direct current at 220 V., or alternating current, through a resistance with which the potential could be varied between 10 and 220 V. The current passing through the animals was registered by milliammeter. Copper electrodes were attached to the forelegs of mice weighing 20–25 gm., the shaved limbs of which had been moistened by a solution of sodium chloride. The mice were cooled by Giaja's method. The temperature of the colon was registered by a thermistor thermometer.

Table 1 summarizes our results, from which it can be seen that hypothermia has a protective action. Increasing the potential enabled the hypothermic animals to withstand a higher current. We found that with a direct current hypothermic animals withstood a current lethal for controls at only 150 V.; whereas with alternating current, the lethal current was obtained at a potential of 120 V. Histological examination of the mice which were killed by the electric current revealed no essential or characteristic changes in the nervous system or in the heart.

Table 1. Effect of Electric Shock on Normal and on Hypothermic Mice

Current	Colonic temperature	Current passed through the animals (mean value)	Dead/shocked
Direct current (80 V.; 10 sec.)	37–39° C.	62 m.amp. ♂	46/50
	37–39° C.	100 m.amp. ♀	48/50
	15–20° C.	40 m.amp. ♂	1/50
	15–20° C.	56 m.amp. ♀	3/50
Alternating current (80 V.; 10 sec.)	37–39° C.	100 m.amp. ♂	50/50
	37–39° C.	118 m.amp. ♀	50/50
	15–20° C.	40 m.amp. ♂	1/50
	15–20° C.	55 m.amp. ♀	2/50

The conductivity of males under normal conditions is $7 \cdot 8 \times 10^{-4}$ ohm^{-1}; in a hypothermic state it is 5×10^{-4} ohm^{-1} (decrease, 36 per cent). The conductivity of control female mice is $12 \cdot 5 \times 10^{-4}$ ohm^{-1}, that of cooled females 7×10^{-4} ohm^{-1} (decrease, 44·1 per cent). Putting the mean temperature of mice as 20° C., the thermal coefficient of male mice is 1·86 per cent/degree, that of female mice is 2·2 per cent/degree, which corresponds very well with the thermal coefficient of ion activity. Therefore the main reason for the decrease in conductivity is probably the change of ion activity with temperature.

Effect of Muscular Activity prior to Venepuncture on the Respiration of Leucocytes *in vitro*

During an investigation of the respiration of human leucocytes we noticed that moderate exercise by the donor prior to venepuncture seemed to be associated with a high rate of leucocyte oxygen consumption. Determination of the oxygen consumption of leucocytes (resuspended in a modified Krebs No. 2 buffer) was made by the direct method in Warburg respirometers at 37° C. Results were expressed as μmoles oxygen consumed per hr. per 10^7 leucocytes, so that the effect of any variation in total white cell count was eliminated.

We therefore compared the oxygen consumption of white blood cells taken before and after exercise from six normal subjects. All were members of the clinical or laboratory staff, aged 18–29 years. The subjects were fasting, and had rested on a bed for 30 min. before the first blood sample was obtained by venepuncture. A moderate walking exercise lasting 3–4 min. was then performed. Leucocytes obtained by venepuncture 5 min. after the walking exercise showed increased oxygen consumption 36–71 per cent above the control value before exercise (Table 1). Estimations of the subjects' oxygen consumption

Table 1. Effect of Exercise on Respiration of Leucocytes *in vitro*

Subject	Estimated surface area (m.²)	Before exercise		After exercise		Percentage increase in oxygen consumption	
		White blood cell oxygen consumption*	Subject's oxygen consumption†	White blood cell oxygen consumption	Subject's oxygen consumption	White blood cells	Subject

* μmoles oxygen/hr./10^7 leucocytes. † ml. oxygen/min.

(using a Benedict–Roth apparatus) confirmed that exercise had been moderate. Differential white cell counts were made before and after exercise: there was no significant alteration in the count.

The possibility that the change in leucocyte oxygen consumption was due to venepuncture was considered. Blood samples were taken from three normal subjects, with a similar time interval between samples as before, but without exercise. The change in oxygen consumption between first and second samples was − 11, + 5 and − 3 per cent.

We conclude from these results that: (1) a substance may appear in the blood as a result of moderate exercise which has the property of stimulating the metabolic rate of the leucocytes *in vitro*; (2) in previous work on respiration of leucocytes the effect of preceding muscular activity was not taken into account, and this may explain some of the discordant results reported.

Effect of Acetylcholine on the Membrane Resistance and Threshold of Atrial Muscle Fibres

THERE is substantial indirect evidence that acetylcholine increases the conductance of the atrial muscle membrane probably by increasing the permeability to K+ and Cl−[1,2]. In addition, acetylcholine has an effect on the sodium-carrying system[3]. These two actions form the basis of a hypothesis suggested by us[3] for the possible explanation of the excitatory and inhibitory actions of acetylcholine on atria described by Burn[4].

It seemed vital to determine what effect acetylcholine had on the membrane resistance and on the threshold. We have attempted the following experimental techniques to examine this problem. (*a*) One microelectrode was used for stimulating and recording; (*b*) a double-barrelled microelectrode was used and (*c*) two microelectrodes (stimulating and recording) were inserted into the same muscle fibre. All methods proved extremely exacting. Indeed, Trautwein, Kuffler and Edwards[1] discarded methods (*a*) and (*c*) and used a method employing external electrodes which demonstrated changes in the membrane resistance and time constant. They were not able to determine changes in the threshold. In the present work method (*a*) was abandoned, method (*b*) is being further developed and method (*c*) was found to be entirely successful in only one of twenty experiments.

In view of the implications of the findings, we are reporting the results of this single experiment.

Two microelectrodes were inserted into a single muscle fibre of rabbit right atrium driven electrically at a rate of 3·6/sec., current being passed through one electrode and the resultant membrane potential changes recorded through the other. Square pulses of depolarizing current applied through the stimulating microelectrode between every eighth–ninth externally applied stimuli produced membrane changes of the form shown in Fig. 1. Acetylcholine 10^{-6} reduced the amplitude and time constant of rise of this potential.

This is interpreted as being direct evidence of a fall in membrane resistance. There was no concomitant change in membrane resting potential or maximum rate of depolarization. At the same time the threshold was decreased, that is to say, the membrane had to be depolarized to a lesser extent to initiate an extra response. A slight increase in current was required to stimulate. This was due to the fact that the decrease in threshold did not entirely compensate for the fall in membrane resistance.

The decrease in threshold could be due to a direct effect on the sodium-carrying system. Alternatively, it is conceivable that if the membrane time constant were of the same order or slightly greater than that of the inactivation of the sodium-carrying system, then a reduction in time constant of the membrane to a value lower than that of the sodium inactivation could result in a decrease in threshold.

We are endeavouring to confirm these findings with the double-barrelled microelectrode technique; but as they further support our recently suggested hypothesis[3] it does seem that in considering the

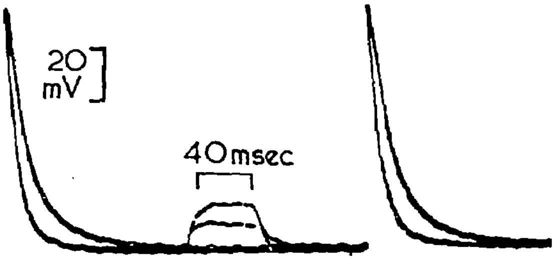

Fig. 1. This consists of two superimposed photographs, one before and one after the application of 10^{-6} acetylcholine to isolated rabbit right atrial muscle. A recording and a stimulating electrode are inserted into the same cell. The changes in membrane potential following the application of a current pulse via the stimulating electrode is shown between the eighth–ninth action potentials. The amplitude of the responses are just subthreshold (the larger is before the acetylcholine was applied). It can be seen that the acetylcholine has decreased the time constant of the membrane and decreased the threshold, the duration of the two action potentials being decreased at the same time. (Photograph retouched to correct losses in photography)

effects of acetylcholine on atrial muscle one must take into account not only its effects on membrane resistance (K^+ permeability and rate of repolarization) but also the possible direct–indirect effects on depolarization mechanisms.

Sites of the Physiological Breakdown of the Red Blood Corpuscles

IF erythrocytes labelled with iron-59 in their hæmoglobin are transfused from a donor rabbit to a sister animal, and, after a lapse of some hours, the labelled iron is located in the depot iron fraction, in the ferritin and hæmosiderin of organs, we can conclude that erythrocytes were broken down in these organs.

Since the plasma contains no radioiron, the only source of iron-59 present in the depot iron fractions is radioiron liberated from the transfused labelled red corpuscles.

This line of thought induced us to replace red corpuscles contained in 20 ml. of rabbit blood with the corresponding amount of washed red blood corpuscles all labelled with iron-59 from a sister animal.

The results of one of our experiments are given in Table 1.

Table 1. DISTRIBUTION OF IRON-59 IN THE DEPOT IRON (FERRITIN + HÆMOSIDERIN) OF ORGANS

Organ	Total depot iron (mgm.)	Total radio-activity of depot iron (c./min.)	Depot iron radioactivity per gm. organ (c./min./gm.)	Percentage distributed *
Liver	10·9	9,830	154	8·4
Spleen	0·681	2,340	2,600	2·0
Red bone marrow†	5·9	86,500	2,470	74·0
Kidneys	0·850	4,300	314	3·7
Lungs	0·590	9,250	1,050	7·9
Small intestine	0·807	4,600	79	4·0

* Total radioactivity of the depot iron of all organs investigated = 100 per cent.

† The total amount of the red bone marrow was assumed to comprise 1·1 per cent of the body-weight.

It is seen that the depot iron-59 content of 1 gm. of spleen is higher than that of an equal amount of any other organ studied. Considering the total organs, however, the red bone marrow contains more iron-59 than any other organ investigated. In seven other experiments the ratio of the depot iron-59 content of the red bone marrow and the spleen varied between 6 and 50, the corresponding ratio of the red bone marrow and liver figures being 0·6–9.

In view of the fact that the spleen of the rabbit is very small, its weight being only 1/35 that of the red bone marrow, we cannot expect the ratio of the amount of erythrocytes broken down in the bone marrow and the spleen to be as high in other mammalian species as it is in the rabbit. Our results suggest, however, that even in man presumably a third or more of the number of erythrocytes terminating their physiological life-cycle is broken down in the bone marrow.

Miescher[1] published results similar to those reported here. He transfused red corpuscles labelled with chromium-51 into rabbits and found that, after a lapse of 25–35 days, about 30–75 per cent of the chromium-51 was located in the bone marrow, 23–49 per cent in the liver and 6–40 per cent in the spleen. The finding of Miescher that the spleen accumulates a larger percentage of the chromium-51 than found by us is possibly due to a large part of the chromium-51 leaking out from intact erythrocytes. A part of this chromium may accumulate in the spleen. We arrived to the same conclusion as Miescher concerning the importance of the bone marrow for the physiological breakdown of the red corpuscles. In this connexion it is of interest to recall that Mann *et al.*[2] found that the main part of the bilirubin is formed in the bone marrow.

The interest taken by Prof. G. Hevesy in this investigation is gratefully acknowledged.

Anticholesterol Activity of α-Lipoic Acid

SINCE α-lipoic acid is known to affect lipid metabolism, we have investigated the effect of this acid on the lipid content of plasma, liver and aorta from rabbits which had been fed on a diet containing an excess of cholesterol[1]. Rabbits weighing 2·5–3 kgm. were divided into four groups, each containing five animals. Group *A*, the control group, received a diet of ordinary commercial rabbit food. Each animal in groups *B*, *C* and *D* received this diet, supplemented for seven days with 1 gm. daily of cholesterol mixed with 9 gm. of shredded carrot. Group *B* received no further treatment. Group *C* received daily intramuscular injections of α-lipoic acid (5 mgm./kgm. of the sodium salt in saline). Group *D* received the same treatment as *C*, except that the injections were not started until the day after the high cholesterol diet had been stopped. After fifteen days from the start of the experiment, the animals were killed by bleeding, and samples of blood, liver and aorta were taken aseptically and weighed. Total lipids, phospholipids and neutral lipids were determined by the method of Bloor[2], and cholesterol by the method of Schoenheimer and Sperry[3].

The results (Table 1) show that the high cholesterol diet alone (group *B*) caused a clear-cut increase in plasma total lipids and cholesterol, and a less marked increase in plasma phospholipids and neutral lipids. The liver lipids showed a similar behaviour, but here the increase was larger for cholesterol and neutral lipids than for phospholipids. The aorta cholesterol was also increased, but phospholipids and total lipids were not much changed.

Table 1. Lipid Content from Tissues from Rabbits fed on a Normal Diet (Group *A*), on a High Cholesterol Diet (Group *B*) and on a High Cholesterol Diet and treated with α-Lipoic Acid (Groups *C* and *D*)
Values are given in gm./100 gm. or ml., as means ± standard error

Group	Tissue	Phospholipids	Neutral lipids	Total cholesterol	Total lipids
A	Liver	3·79 ± 0·51	0·33 ± 0·06	0·19 ± 0·03	4·67 ± 0·41
	Plasma	0·16 ± 0·01	0·13 ± 0·01	0·11 ± 0·02	0·46 ± 0·04
	Aorta	1·03 ± 0·09	11·31 ± 1·16	0·19 ± 0·02	12·68 ± 1·36
B	Liver	3·94 ± 0·56	1·24 ± 0·08	2·24 ± 0·31	8·72 ± 0·94
	Plasma	0·57 ± 0·06	0·49 ± 0·06	1·33 ± 0·14	2·98 ± 0·32
	Aorta	1·09 ± 0·13	9·71 ± 1·07	1·87 ± 0·22	13·18 ± 1·68
C	Liver	3·87 ± 0·49	0·37 ± 0·06	0·39 ± 0·05	5·48 ± 0·67
	Plasma	0·24 ± 0·02	0·15 ± 0·01	0·26 ± 0·03	0·89 ± 0·11
	Aorta	0·98 ± 0·08	9·46 ± 0·89	1·24 ± 0·17	12·46 ± 1·38
D	Liver	3·41 ± 0·58	0·46 ± 0·04	0·62 ± 0·13	6·19 ± 0·72
	Plasma	0·37 ± 0·04	0·31 ± 0·03	0·72 ± 0·08	1·80 ± 0·21
	Aorta	0·95 ± 0·12	10·92 ± 1·27	1·64 ± 0·16	12·59 ± 1·34

Treatment with α-lipoic acid from the beginning of feeding with the high cholesterol diet (group *C*) limited the increases in the lipids of the plasma, liver and aorta to a much smaller extent. When the treatment with α-lipoic acid was started at the end of the high cholesterol feeding (group *D*) it produced a similar though somewhat smaller effect. Even so, the plasma cholesterol values were only about half those of animals which had received cholesterol but no α-lipoic acid.

Effect of Testosterone Propionate upon the Incorporation of Labelled Glycine into Homogenates of Mouse Kidney

It was shown recently[1] that the rate of incorporation of glycine-1-^{14}C into kidney slice protein of *A*/*Jax* mice treated with testosterone propionate was significantly higher than into slices from untreated animals. The maximum increase (35–80 per cent) appeared 48 hr. after beginning daily injections of 1 mgm. testosterone propionate, after which the difference between the treated and control series gradually disappeared. A study of some of the characteristics of this response revealed that the difference in incorporation-rates was greatest at low glycine concentrations, and diminished when the glycine concentration of the incubation medium was raised to 4–8 m*M*. It was postulated that under these conditions the effect of this steroid was to facilitate the intracellular accumulation of glycine from a relatively glycine-deficient environment.

As a test of the above hypothesis, experiments were conducted to compare the effects of testosterone propionate upon incorporation of glycine by slices and homogenates of mouse kidney. Female *A*/*Jax* mice (from Jackson Memorial Laboratories, Bar Harbor, Maine) were given two injections of testosterone propionate (0·1 ml. of a solution containing 10 mgm./ml. in sesame oil) 24 hr. apart, and killed 24 hr. after the second injection. The kidneys were removed and weighed; one was sliced and the slices incubated for 2 hr. in Krebs–Ringer phosphate containing isotopic glycine. The other kidney of a pair was homogenized in nine times its weight of the same medium previously cooled to 0°, and the homogenate incubated for 30 min. The bath temperature was 38·4°. After incubation, the slices were removed, blotted and processed as described previously[1]. The reaction in the flasks containing homogenate was terminated by the addition of 2/3 volumes of 25 per cent (w/v) trichloracetic acid. The precipitate was redissolved in dilute alkali and reprecipitated four more times with 5 per cent trichloracetic acid. Before the last precipitation, 10 mgm. non-radioactive glycine was added to ensure removal of adsorbed glycine. The protein precipitated by trichloracetic acid was washed successively in water, acetone, a mixture of chloroform, ethyl ether and ethanol (1 : 1 : 2), and benzene, and finally plated for counting from benzene. Each sample was counted long enough to limit the counting error to a maximum of 5 per cent.

Increase (per cent)		8	36	57

* The medium used for these experiments contained 1·19 m*M* glycine, specific activity 0·17 mc./m*M*.

† Micromoles of glycine carbon incorporated per gm. protein per hr. Average ± standard error.

Results obtained in two experiments, in which a total of 35 animals was used, are summarized in Table 1. It is clear that although incorporation into mouse kidney homogenate is less than one-tenth as rapid as incorporation into slices, the two processes are stimulated to approximately the same degree by administration of androgen. That the effect of testosterone propionate is specific for incorporation into kidney protein is indicated by the results in Table 2, wherein it may be observed that incorporation by mouse liver homogenate is unaffected by testosterone propionate.

As noted above, earlier experiments with kidney slices showed that the effect of testosterone propionate upon incorporation decreased with increasing glycine concentration. Thus, in one series of experiments, the average increases in incorporation-rates for treated animals were approximately 47 per cent and 13 per cent for concentration ranges of 0·125–1·0 m*M* and

* Micromoles of glycine carbon incorporated per gm. protein per hr. Ave. ± S.E. Numbers in parentheses indicate the number of kidneys used for each concentration.

4·0–8·0 mM, respectively. In contrast, the effect of testosterone propionate upon incorporation in homogenates is not significantly affected by changes in glycine concentration within these limits (Table 3).

Our results do not support the hypothesis that stimulation of glycine incorporation by androgen is mediated through an effect upon a concentrative process operating at the level of the cell membrane, since such an effect should be inoperative in cell-free systems. An analogous process, functioning at the subcellular particulate level, is not excluded, however. In view of the considerable difference between incorporation-rates found for slices and homogenates, as well as the difference in the effect of substrate concentration upon the response to testosterone propionate, there remains the possibility that another androgen-sensitive, concentration-dependent component of the incorporation process disappears upon homogenization. Further experimentation, involving studies of the effects of testosterone propionate upon intracellular amino-acid levels, may provide an answer to this problem.

Other anabolic steroids, including testosterone, androsterone, methyl testosterone and methylandrostenediol, also increase the rate of incorporation into mouse kidney homogenates. Hydrocortisone, on the other hand, was distinctly inhibitory, while deoxycorticosterone was devoid of appreciable effect.

Ribonuclease Activity and Ribonucleic Acid Content of Homologous Human Normal and Cancer Cells

A RELATIONSHIP between the level of ribonuclease activity and ribonucleic acid content has recently been found to exist in the human placenta[1] and in hyperplastic bone marrow of the mouse[2]; such a relationship has also been shown to exist in different normal organs of the mouse[3], as well as different epitheliomas in mice or rats[4]. On the other hand, results obtained with solid[4] and ascites tumours[5] suggest that cancerous epithelium might have less ribonuclease activity than a normal one. We have undertaken a study of the properties of the human uterine cervix, from which homologous normal and cancerous tissues can easily be obtained.

In the present work, superficial biopsies of the uterine cervix epithelium were removed from human uteri presenting a stage I or II carcinoma. In each case, a biopsy was also taken from nearby normal tissues of the same cervix. Each sample was homogenized in distilled water. An aliquot was treated with 0·15 N sulphuric acid for 1 hr., and used for the estimation of ribonuclease activity. Another sample was used for the determination of nucleic acids and protein content by the methods already described[3].

The results obtained with these samples, together with samples taken from non-cancerous patients, are shown in Fig. 1. It can be seen that there is a significant correlation between ribonuclease activity and ribonucleic acid content (per unit of protein) for normal and cancerous tissues. The correlation is, however, different in the two cases; for the same ribonucleic acid/protein ratio in both cases, the ribonuclease activity/protein ratio is lower in cancer cells. It can also be seen that, as a rule, the tumour cells contain more ribonucleic acid per unit of protein than the normal cells; they show less ribonuclease activity than the homologous normal control cells. These results, although they are difficult to evaluate owing to the heterogeneity of the material used, suggest that ribonuclease probably plays an important part in cellular ribonucleic acid metabolism.

In respect of cancer cells, it should be noted that exogenous ribonuclease produces a marked inhibition of the growth of spontaneous mammary carcinoma in $C+$ mice[6] and of certain experimental tumours[6,7], while it has no effect on the normal tissues of the host. There may be a correlation between these

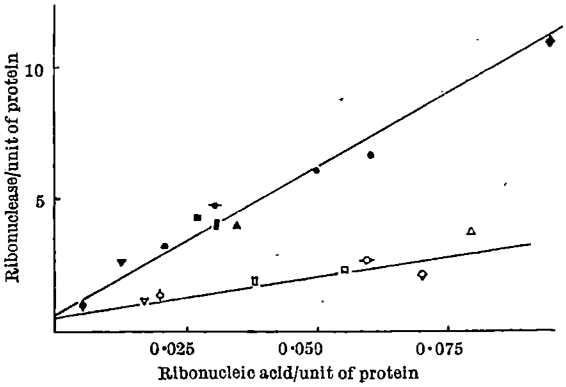

Fig. 1. Relations between ribonuclease activity (measured at pH 5) and ribonucleic acid content of homologous normal and cancerous epithelium in the human uterine cervix. Upper curve, normal epithelium; lower curve, cancerous epithelium. Black signs, normal tissues; white signs, cancerous homologous tissues.

findings and the fact that activity of ribonuclease is lower in neoplastic than in normal tissues.

Since the action of exogenous ribonuclease on ascites tumour cells *in vivo* and *in vitro*[8] begins with a stimulation of ribonucleic acid synthesis and an increase in pyrimidine metabolism, endogenous ribonuclease activity might be related to a selective orientation of the metabolism of ribonucleic acid; if so, the decrease of ribonuclease activity observed in the cancerous uterine cervix might correspond to different ribonucleic acid metabolisms in normal and in cancer cells.

Retention of Sodium-22 in Rat Bone

Three groups of male rats, of about 50, 150 and 300 gm. body-weight respectively, were placed on a low sodium diet, and 5 µc. sodium-22 chloride per kgm. body-weight injected intraperitoneally on day 1. On days 3 and 5 a further injection of 2 µc. per kgm. was given, and on day 7 all were replaced on the stock diet (0·5 per cent sodium). Six female rats each weighing 250 gm. were mated on day 1, and the diet and sodium-22 administered as above; three were replaced on the stock diet on day 14 and the others maintained on the low sodium intake until term. Approximately each 10 days, commencing on day 11, one male from each group was bled from the tail to obtain a plasma sample; humeri and femora were then removed and scraped as clean as possible and weighed. The four bones from each animal were placed in 0·05 *M* silver nitrate in 5 *N* nitric acid, and after standing in the cold for some days the mixture was heated at 100° C. to effect complete solution of organic matter. This method was designed to avoid formation of volatile organic compounds containing chlorine[1,2].

Total sodium was measured by EEL flame photometer, sodium-22 was counted with a scintillation counter, and chloride was measured by Volhard's method[3]. The sodium in the extracellular fluid of the bone was then calculated from plasma sodium and chloride and bone chloride, and its radioactivity from the plasma radioactivity. These values were subtracted from the total sodium and radioactivity found in the bones to obtain an estimate of the true bone sodium and radioactivity. From tables[4] estimates were obtained of the total bone-weight of the rats at the various times, and from these and the radioactivity measurements estimates have been made of the percentage retention of sodium-22 in the total skeleton (see Table 1). While on the low sodium diet, the rats gained weight less rapidly than the tables suggested, so that the estimates of total bone activity may be slightly too high, especially for the first two times. In some large rats the bones of which were analysed 24 hr. after injection about 10 per cent of the administered dose was initially deposited in the skeleton.

Only two females of each group delivered litters, and the young were allowed to grow to about 100 gm. body-weight. Then the blood and bones of six young from each group were treated as above, pooling all the samples in each of the two groups. When the mothers had been exposed to the sodium-22 and low sodium diet during only the first two weeks of pregnancy, the mean retention of the isotope in the four bones of each offspring two months later was 10^{-5} µc. ($P < 0·01$); this corresponds to approximately 0·005 per cent of the dose administered to the mother per fœtus. When the mothers had been kept on the low sodium diet throughout pregnancy, the mean retention of sodium-22 in the four bones of the offspring was 3×10^{-5} µc. ($P < 0·001$), or approximately 0·015 per cent of the dose per fœtus. There was no demonstrable sodium-22 in the plasma of any of these offspring at death.

It is impossible to draw any detailed conclusions from these preliminary figures, but some sodium-22 was laid down relatively permanently in the growing bones of the rats—more in the younger animals the growth-rate of which was higher. This would appear to be about 0·5–1 per cent of the administered dose, or of the order of 5–10 per cent of the fraction originally laid down in the bone at the end of 24 hr. The specific activity of the plasma declined far more rapidly as expected, with a half-period of about three days in the large rats and one and a half days in the small ones. Whether the whole of the isotope would ultimately have been lost, as suggested by accumulation experiments[5], cannot be decided from the above figures.

How relevant these findings with rats (the bones of which were still growing during the entire experimental period) are to adult humans is not known, but certainly the growing bone of the child may be expected to behave in a similar manner.

The above work was performed during the tenure of a Nuffield Foundation Dominion Travelling Fellowship at the Department of Chemical Pathology,

Lesions in the Hypertensive Rat Kidney produced by Hydralazine

THE use of hydralazine (1-hydrazinophthalazine) for the control of human hypertension was followed by the recognition of serious and undesirable side-effects. The similarity of some of these effects to disseminated lupus erythematosus led to the investigation of the influence on the normal dog of toxic doses of this drug[1,2]. These experiments failed to provide satisfactory evidence for the production in the dog of an experimental model of disseminated lupus erythematosus.

To reproduce more closely the conditions under which the desired changes are found clinically, increasingly large amounts of hydralazine have been given by single daily intramuscular injection to rats previously subjected to a regime shown to cause systemic hypertension. The regime comprised left nephrectomy, the subcutaneous implantation of 100 mgm. of slowly absorbed deoxycortone acetate, and the substitution for drinking water of 1 per cent sodium chloride. The development of hypertension was suppressed by the hydralazine injections, each injection being followed by an abrupt fall in blood pressure succeeded by a linear rise continuing throughout the following 24 hr.

In these circumstances the intact kidneys of the treated animals were found to contain a surprisingly large number of focal glomerular lesions. The lesions were usually confined to one segment of the glomerular tuft, and varied from focal necrosis, with aneurysmal capillary dilatation, to segmental replacement fibrosis; they were not accompanied by arterial or arteriolar changes.

In control animals subjected to the same hypertensive regime and injected daily with an inert fluid the tubular effects of deoxycortone were recognized but were accompanied only by glomerular enlargement and seldom by the characteristic glomerular lesion seen when larger amounts of deoxycortone are more rapidly absorbed. Similar deoxycortone effects were also present in the hydralazine-treated animals.

Hydralazine may therefore influence the integrity of the rat glomerulus under certain carefully defined conditions. The effect is indirect, and is observed neither in the normal animal nor in the animal from which one kidney has been removed but which has received no deoxycortone. The glomerular damage clearly cannot be satisfactorily explained in terms of sustained hypertension, nor is it likely to be a result of the gradual rise in blood pressure which is the sequel of the acute hypotension following each daily injection of hydralazine. It is, however, possible that the damage may be directly related to the daily hypotensive episode.

The production of these lesions in the rat glomerulus is considered to be of importance, partly because their recognition provides the first satisfactory evidence of a damaging effect of hydralazine upon the kidney in experimental hypertension, and partly because of the suggestion that episodic hypotension may be the immediate causative agent. In addition, the experiment provides some evidence for the suggestion that glomerular lesions due to deoxycortone can be distinguished from those due to variations in blood pressure, and thus that the glomerular effects of deoxycortone are not necessarily due to hypertension.

Determination of Transaminase Activity of Serum Protein Fractions separated by Paper Electrophoresis

THE electrophoretic mobility of glutamic–oxalacetic acid transaminase in blood serum has been found to be between those for α_2- and β-globulins[1]. In our experiments[2] the glutamic–oxalacetic acid transaminase was associated mainly with α_2-globulins. This communication deals with this transaminase and glutamic–pyruvic acid transaminase and their relations to serum protein fractions.

Blood sera of six patients with characteristic activities of both enzymes were studied. 0·2-ml. samples of sera were electrophoretically separated on Whatman No. 1 filter paper strip (14 cm. × 35 cm.) in 5 hr. Barbital buffer of *p*H 8·6, ionic strength 0·1, was used with a voltage of 350 V. and a current of 0·5–0·8 m.amp. per cm. The marginal sections (3 cm.) were stained for proteins with bromthymol blue. The middle section of paper was cut into corresponding protein fractions and tested for their transaminase activity. The method for simultaneous determination of glutamic–oxalacetic acid and glutamic–pyruvic acid transaminases with an incubation mixture containing glutamate, oxalacetate and pyruvate was used. The action of enzymes was followed by determining the formation of L-aspartic acid and L-alanine, which have been estimated by the ninhydrin method after electrophoretic separation from aliquots of the incubation mixture[3]. In other experiments the middle section was, first of all, cut longitudinally into two identical parts and these were afterwards divided into strips containing the single protein fractions. One part of these strips was incubated with α-ketoglutaric and L-aspartic acid (both kindly supplied by the California Foundation for Biochemical Research, Los Angeles) and the other one with α-ketoglutaric acid and L-alanine. The activities of the glutamic–oxalacetic acid and glutamic–pyruvic acid transaminases in single protein fractions were assayed by hydrazone methods[4,5].

The distribution of transaminases on blood serum protein fractions is presented in Table 1.

Table 1

Diagnosis	Percentage of total Glutamic–oxalacetic acid transaminase activity associated with serum protein fractions					Glutamic–pyruvic acid transaminase				
	Globulins					Globulins				
	γ	β	α_2	α_1	Albumins	γ	β	α_2	α_1	Albumins
Infectious hepatitis (2 cases)										
Obstructive jaundice (metastatic carcinoma)	2	7	82	2	7	7	81	8	1	3
Acute myocardial infarction (3 cases)	7	12	75	5	1	18	43	23	8	8
Range of values	(0–8)	(4–17)	(67–89)	(0–10)	(0–10)	(5–12)	(41–90)	(2–36)	(0–21)	(0–19)

The results show that in the pathological sera used the activity of glutamic–oxalacetic acid transaminase is mainly bound with α_2-globulins, and that of glutamic–pyruvic acid transaminase with β-globulins.

Relationship between Porphyrin and Isoniazid Resistance of *Mycobacterium avium*

IT has been reported that a decrease in catalase activity is observed when tubercle bacilli acquire isoniazid resistance[1], and later it was demonstrated that hæmin is required for growth by some of these resistant strains[2]. We have found that the amount of a red fluorescent substance in sensitive strains of *M. avium* (Jûchô, Takeo and 607) is smaller in strains resistant to isoniazid: while the sensitive organism contained 5·5 mgm. red compound/kgm. bacteria, those which were resistant to 250γ isoniazid contained only 2·1 mgm. compound/kgm. bacteria. The sensitive and resistant strains discussed in this communication were cultured in a glycerin–bouillon medium containing no isoniazid.

The red fluorescent substance was extracted with acetone from the organism. The acetone extract was concentrated *in vacuo* and the concentrate was diluted with two volumes of water, then extracted with ether. The ether extract was evaporated *in vacuo* and the residue was purified by the conventional methods for porphyrin extraction. The red material thus obtained had absorption maxima at 624, 597, 568, 529, 495 mμ (in ether solution); relative intensities $495 > 529 > 568 > 624 > 597$. The paper chromatographic analysis of this compound gave evidence that the compound was coproporphyrin III ester, a 4-carboxyporphyrin ester[3–5]. The hydrochloric acid number of the hydrolysis product was 0·09.

Todd[6] has isolated coproporphyrin III tetramethyl ester from *M. karlinski* and also reported the presence of the same porphyrin in *M. stercoris* and *M. smegmatis*. The present porphyrin was shown to be identical with that of *M. smegmatis* by paper chromatography. On account of the low yield we could not obtain the red substance in a crystalline state, but the above evidence indicates that the substance is coproporphyrin III tetramethyl ester.

We have added the free coproporphyrin obtained by the method described above to the medium of the isoniazid-resistant *M. avium* (250γ resistant Jûchô strain) and measured the catalase activity by the method of Euler and Josephson[7]. The value thus obtained was 1·236; on the other hand, the value for the resistant bacterium cultivated without coproporphyrin was 0·115. Thus the value was more than ten times greater in the presence of the porphyrin but no difference in the degree of resistance resulted. This evidence suggests that there is no decisive relation between isoniazid resistance and the lack of catalase activity of the bacteria.

We are greatly indebted to Profs. Y. Hirata, K. Hotta and T. Mori for valuable advice. We are also grateful to T. Shoda for invaluable assistance and to Prof. Y. Yamamura, who kindly measured the catalase activity.

The Latent Period after Infection with Tobacco Mosaic Virus and Virus Nucleic Acid

THE process of infection by plant viruses is not so well known as that for animal viruses and bacteriophages. The main reasons are that tissue cultures are not yet available in which all cells can be uniformly infected and that the methods for determination of the activity are not sensitive enough. Experiments of this kind have been carried out with total plants or pieces of leaves. Siegel *et al.*[1] studied the early events of infection with tobacco mosaic virus by an indirect method, measuring the ultra-violet sensitivity of infective centres in *Nicotiana glutinosa*. An increase in ultra-violet resistance occurred 5 hr. after infection at 20° C. This time can be considered as the lag phase. Other results to demonstrate the increase of virus concentration directly are obscured by the fact that the adsorbed virus which has not penetrated and therefore does not participate in the infection is not removed from the surface of the leaves[2]; further, the methods of determination were not sensitive enough[3].

For the detection of small amounts of viruses the bioassay is by far the best method. Using the local lesion test on *Nicotiana glutinosa* we found that a minimal concentration of 10^{-12}–10^{-13} gm. tobacco mosaic virus/ml. was detectable. 25 leaves powdered with 'Carborundum' were used for each dilution. It seemed probable that the minimal infective dose is smaller in plants reacting with systemic symptoms. Young plants of *Nicotiana tabacum* (Samsun) were inoculated with tobacco mosaic virus solutions, again adding 'Carborundum'. The effect was variable, but using a considerable number of plants, we found a 50 per cent infection with a dilution of 10^{-16} gm. tobacco mosaic virus/ml. We applied 5 ml. per plant and this dose is equal to 10 virus particles (Table 1). This test is rather laborious and several precautions were necessary to avoid misleading results. The test may only be used for qualitative purposes.

Table 1. INFECTIVITY OF DILUTIONS OF TOBACCO MOSAIC VIRUS ON *N. tabacum*. CONTROLS WERE INOCULATED WITH PHOSPHATE BUFFER

Tobacco mosaic virus conc. (gm./ml.)	Infected plants / Total number	Percentage infected
10^{-8}	22/25	88
10^{-10}	4/25	16
10^{-12}	29/40	72
10^{-14}	51/60	85
10^{-16}	37/75	54
10^{-18}	0/10	0
10^{-20}	0/10	0
Control	0/63	0

By these methods of bioassay and other methods we have investigated the process of infection in young plants of *Nicotiana tabacum* (Samsun). We inoculated three leaves of each plant with 10^{-6} gm. tobacco mosaic virus/ml. in 0·1 *M* phosphate buffer, *p*H 7·2. The leaves were previously dusted with 'Carborundum'. In order to remove the adsorbed virus particles, the leaves were rinsed with water and then with diluted tobacco mosaic virus antiserum. The infected plants were maintained in a thermostat at 23° C. and had constant illumination. After certain intervals the primarily infected leaves of groups of five plants were harvested. The homogenates of these samples were tested on *Nicotiana glutinosa*, as described above. By means of a reference curve, the amount of virus per gm. leaves was calculated from the number of local lesions.

A typical experiment which is easily reproducible is shown in Fig. 1. After the latent period, multiplication is rapid, but it slows down when a concentration of about 10^{-7} gm. virus/ml. is reached in the tissue. For determining the latent period the curve must be extrapolated to the time when the first complete virus particle appears in the leaf. This corresponds to a concentration of 7×10^{-17} gm. tobacco mosaic virus/gm. leaf. The extrapolation led to a latent period of about 30 hr. Even with the very sensitive test in *Nicotiana tabacum*, we never found an infective virus particle before the end of the latent period. In the first 30 hr. the virus concentration is probably less than 10^{-16} gm./ml. This indicates that there is a true latent period after infection. The latent period in *Nicotiana tabacum* seems to be much longer than that in *Nicotiana glutinosa* as found by the ultra-violet method[1].

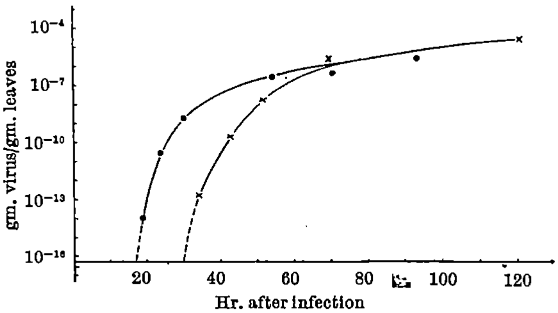

Fig. 1. Increase of virus concentration after infection with tobacco mosaic virus (×—×—×) and virus ribonucleic acid (●—●—●) in *Nicotiana tabacum*

Gierer and Schramm[4] showed that the ribonucleic acid isolated from tobacco mosaic virus by phenol extraction is infectious. Therefore it is probable that, in the cell, the external virus protein shell has to be removed before multiplication can start. If this removal is a slow process, the latent period should be reduced after infection with the isolated virus ribonucleic acid. We infected tobacco plants with ribonucleic acid solutions of the same infectivity as in the previous experiments with tobacco mosaic virus. Sometimes the ribonucleic acid and tobacco mosaic virus experiments were run parallel in the same thermostat. From Fig. 1 it can be seen that the increase of the activity of the virus occurs 10–12 hr. earlier than after infection with the virus. This is evidence that the release of ribonucleic acid from the virus takes several hours. However, it is not clear why the ribonucleic acid itself has such a long latent period. The events in this remaining latent period require further study. It should be mentioned that, by extraction of the virus particles from the leaves, the virus ribonucleic acid and other precursors can be destroyed by enzymes. Our experiments confirm the results of Siegel *et al.*[1], who also observed a reduction of the lag phase in infection with ribonucleic acid.

Lysis of Fungal Mycelia by Bacterial Enzymes

MANY investigations have been published[1] on lysis of bacterial cells by microbial enzymes, but there seems to be few references to the lysis of fungal mycelia by microbial enzymes. A bacterial strain which caused visible lysis of *Aspergillus oryzae* mycelia has been isolated from soil. This strain belongs to the *Bacillus circulans* species ; it is Gram-negative, with spore-forming rods (spore : oval, terminal to subterminal), motile with peritrichous flagella, it reduces nitrate, is negative to acetylmethylcarbinol, and produces acid from glucose without evolving gas.

When this strain was inoculated into a flask culture of *A. oryzae* (in Czapek–Dox medium), which had been previously shaken for ·24 hr. at 30° C., almost all the mould mycelia disappeared after 80 hr. shaking at 30° C. The culture fluid was centrifuged at 7,000*g* for 30 min. to remove bacterial cells grown in the mixed culture, and a pale brownish supernatant was obtained.

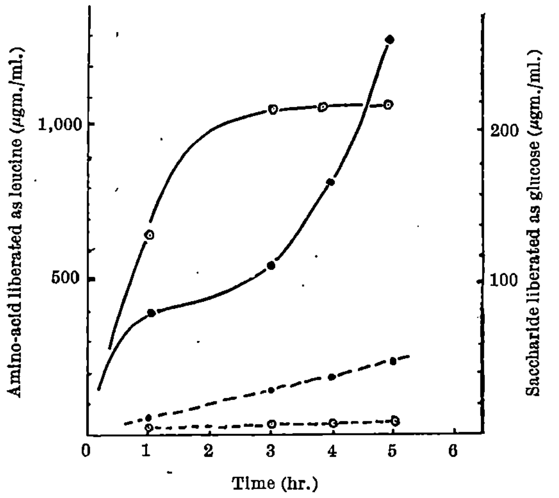

Fig. 1. Lytic action of the enzyme on living mycelial cells. 1 gm. of the living mycelial cells was suspended in 20 ml. of the lytic enzyme solution, and the mixture was incubated at 37° C. ●—●, Amino-acid; ⊙—⊙, saccharide; ●---●, amino-acid (control); ⊙---⊙, saccharide (control)

The supernatant was brought to 0·7 saturation with ammonium sulphate and stored in an ice-box overnight. The precipitate was collected by centrifugation and dissolved in $M/50$ tris-buffer (pH 6·8). The solution was dialysed against the same buffer for 48 hr. at 4° C. 1 gm. (wet weight) of living mycelial cells of *A. oryzae* was suspended in 20 ml. of this enzyme solution and incubated at 37° C. About 5-ml. portions of this mixture were sampled at 1-hr. intervals, and the hexose and amino-acid liberated were determined by the anthron method[2] and by Stein and Moore's method[3] respectively. As control, the boiled (100° C., 5 min.) enzyme solution and living mould cells were used. Fig. 1 shows the experimental results.

The cell walls of the mycelia were then used as the substrate, instead of living mycelia. The cell walls were prepared as follow: mycelia were disrupted by use of a Waring blendor, and disrupted mycelia were then treated with a crystalline bacterial protease (100 μgm./ml.). This mixture was filtered and the residual cell material (cell walls) was washed with water. The cell walls thus obtained were dried *in vacuo* over calcium chloride.

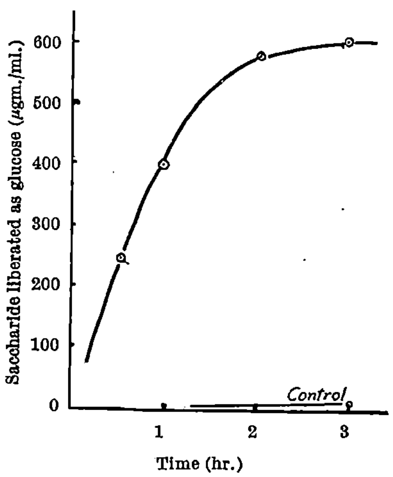

Fig. 2. Lytic action of the enzyme on the cell walls of *A. oryzae*. 25 mgm. of the cell walls was suspended in 10 ml. of the lytic enzyme solution, and the mixture was incubated at 37° C.

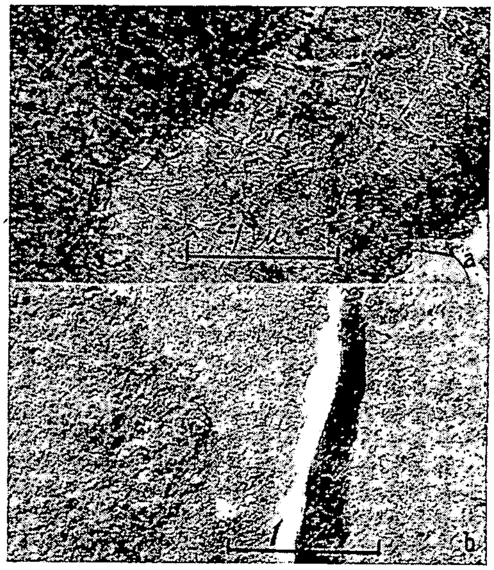

Fig. 3. (*a*) Rough layer of the cell-wall surface before treatment with the lytic enzyme; and the fibrous structure appeared on the inner side of the cell wall. (× 20,000). (*b*) After treatment with the lytic enzyme for 3 hr. The rough layer of the cell wall has disappeared, and the granular layer is observed; the fibrous structure is degraded. (× 20,000)

The course of degradation of the cell-wall material by the crude enzyme preparation from *B. circulans* is shown in Fig. 2, from which it seems that this enzyme acts on the cell walls directly. When treated with this enzyme, the rough surface layer seen before treatment disappeared, and a granular layer not visible before treatment appeared in the electron microscope (see Fig. 3).

This enzyme did not liberate either hexosamine or amino-acid (as detected by paper chromatography), but liberated a saccharide which was precipitated with 50 per cent alcohol. Paper chromatographic methods were used in attempting to identify the saccharide, but the spot remained at the origin. Hence it seems that the saccharide is a polymer of hexoses. The polysaccharide was then hydrolysed with 75 per cent sulphuric acid and neutralized with barium carbonate and chromatographed with pyridine/ethyl acetate/water (1 : 2 : 1). Glucose and galactose were identified in the acid hydrolysate.

It was further confirmed that this enzyme acts on the living mycelial cells of *A. aojae* KS., *Pen. purpurogenum* var., and *Mucor M*-5 but not on *Rhizopus R*-1-8.

We thank Prof. K. Sakaguchi, Dr. M. Amaha and Dr. M. Nomura (University of Tokyo) for their encouragement and guidance.

Enhancement of Mouse-virulence of Group *A* Streptococci by Bactericidal Resorcinols

It seems to be generally agreed that agents capable of enhancing the virulence of bacteria, particularly mucins, do so by interfering with the defences of the host[1-3]. Recently, it was shown[4] that broth or peptone injected intraperitoneally into *W*-Swiss mice even 1 hr. after a non-lethal saline suspension of group *A* streptococci converts the non-lethal dose into an *LD*100, the time-lag pointing again to an action on the host. The present communication brings further evidence in this respect; it also shows that substances bactericidal *in vitro* can act as virulence-enhancing agents *in vivo*.

The resorcinols were the 4-*n* substituted alkyl derivatives, ethyl, propyl, butyl, amyl and hexyl resorcinol[5]. The intraperitoneal injection of 0·5 ml. of a 0·1 per cent saline solution of these compounds is without marked effect on mice.

Two strains of group *A* streptococci were used, one type 12, the other type 22; the *LD*100 was 0·5 ml. of a 10^{-2} saline dilution of culture, the culture itself containing about 2×10^7 viable cells per ml. The organisms were grown in broth consisting of 2 per cent 'Oxoid' peptone, 0·8 per cent 'Oxoid Lab. Lemco' broth powder, 0·2 per cent glucose and 0·2 per cent sodium bicarbonate made up in distilled water, sterilized by Seitz filtration and tubed in 4-ml. lots in ¼ oz. screw-capped Bijou bottles.

Two types of experiment were carried out. First, 18-hr. old cultures of streptococci were diluted 1 in 10 in 0·1 per cent solutions of the various resorcinols and kept, with occasional shaking, at room temperature, 24°, for 30 min., a 10^{-1} saline-dilution of culture serving as control; thereafter *W*-Swiss mice were injected intraperitoneally with 0·5 ml. of the suspensions from which viable counts were made[6]; all control animals and all animals injected with the ethyl and propyl resorcinol suspensions of organisms died. There were no deaths in the groups injected with the organisms exposed to butyl, amyl and hexyl resorcinol. The butyl, amyl and hexyl suspensions were found sterile whereas the ethyl, propyl and saline suspensions still contained approximately the same number of viable organisms.

In the second group of experiments the organisms were not exposed *in vitro* to the action of the resorcinols: instead, mice were first injected intraperitoneally with 0·5 ml. of 10^{-2}–10^{-6} saline dilutions of culture and immediately afterwards with 0·5 ml. of a 0·1 per cent saline solution of the resorcinols; control animals were given intraperitoneally 0·5 ml. of the saline dilutions of culture followed by 0·5 ml. of saline. Under these conditions the resorcinols proved to be not disinfectants but virulence-enhancing agents and a 100- to 1,000-fold decrease of the *LD*100 was observed (Table 1).

Table 1. EFFECT OF 4-*n* ALKYL-SUBSTITUTED RESORCINOLS ON MOUSE-VIRULENCE OF GROUP *A* STREPTOCOCCI

Strain	Alkyl resorcinol	Deaths in groups of 16 mice inoculated with the following culture dilutions*				
		10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}
Cumming Type 22	None-saline control	16	8	0	0	0
	Ethyl	—	8	3	0	0
	Propyl	—	9	5	0	0
	Butyl	—	—	16	13	0
	Amyl	—	—	16	16	11
	Hexyl	—	—	16	16	9
1965 Type 12	None-saline control	16	10	1	0	0
	Ethyl	—	9	7	0	0
	Propyl	—	13	5	0	0
	Butyl	—	—	16	14	0
	Amyl	—	—	16	16	11
	Hexyl	—	—	16	16	12

* Mice injected intraperitoneally, first with 0·5 ml. of the stated saline dilutions of culture, then with 0·5 ml. of saline or of a 0·1 per cent saline solution of an alkyl resorcinol.

Thus it has been shown that the same substance can act both as a bactericide and as a virulence-enhancing agent, depending on the conditions of the experiment, and that in the alkyl resorcinols examined virulence-enhancing activity parallels bactericidal activity. The experiments rule out a true enhancement of virulence of the infecting organism and demonstrate that the action of the resorcinols is on the host.

A Possible Source of Error in the Chemical Detection of Indolyl Acetic Acid in Plants

DURING investigations on the growth substances of fruits of cacao and bananas (*Musa* spp.), it was of interest to find that a substance was present in seeded bananas which gave a pink colour with ferric chloride/perchloric acid or *p*-dimethyl amino-benzaldehyde/hydrochloric acid, corresponding to the R_F of indolyl acetic acid and to the zone of bioassay using the wheat coleoptile straight-growth test. Subsequent experimentation showed that although the straight-growth response was probably due to indolyl acetic acid, the colour reaction was not. The technique of extraction and bioassay was essentially similar to that of Bennet-Clark and Kefford[1] with some minor modifications. Duplicate samples of the acid fraction from seeded banana fruit extracts were developed by the descending method on Whatman's 3 *MM* or No. 1 chromatography paper in *iso*propanol/ammonia/water (10 : 1 : 1). Synthetic indolyl acetic acid was developed as a marker. One sample was bio-assayed by the wheat straight-growth test and the other sprayed with ferric chloride/perchloric acid (1 ml. 0·05 *M* ferric chloride + 50 ml. 5 per cent perchloric acid).

The ferric chloride/perchloric acid spray, on heating, developed a pink or pinkish-purple spot on the chromatogram corresponding to both the zone of growth activity after bio-assay and to the indolyl acetic acid marker. The top half of the chromatogram ($R_F < 0{\cdot}5$) was usually streaked with oxidized polyphenolic substances which could be detected visually without treatment by the brown colour and confirmed by diazotized *p*-nitraniline. It was found that if synthetic indolyl acetic acid was spotted into the brown area, dried and afterwards heated with ferric chloride/perchloric acid, the final colour development was not the more typical pink but pinkish-purple, similar to the colour developed with the banana extracts. The evidence from the R_F behaviour, colour reactions with ferric chloride/perchloric acid and bio-assay activity therefore suggested that the banana auxin was probably indolyl acetic acid.

However, in a detailed series of extractions from bananas of different ages it was noted that in some experiments the colour reaction with ferric chloride/perchloric acid could be obtained but without the corresponding growth activity after bioassay. Luckwill[2] has pointed out the necessity of using more than one developing solvent in order to confirm the presence or absence of indolyl compounds in plant extracts, and of the necessity of critical bioassay. Afterwards the acidic fractions of seeded bananas were run in 70 per cent alcohol and butanol/acetic acid/water (4 : 1 : 5). In 70 per cent alcohol the results were essentially similar to that found with the *iso*propanol solvent except that the growth activity, indolyl acetic acid marker and pink spot developed by ferric chloride/perchloric acid were found in the region of R_F 0·55. However, in butanol/acetic acid/water the zone of the growth activity and indolyl acetic acid marker were found consistently at R_F 0·95, whereas the coloured product developed with ferric chloride/perchloric acid appeared at 0·79–0·80. This evidence indicated that indolyl acetic acid was present in seeded bananas but it was not responsible for the colour reaction with perchloric acid.

In order to confirm the presence of indolyl acetic acid, duplicate samples from the extracts of seeded bananas were first run in *iso*propanol/ammonia and the zone of growth activity from one chromatogram, determined by bioassay of the other, was eluted with ether. The ether extract was concentrated under reduced pressure and re-chromatographed on Whatman No. 1 paper, using distilled water as the developing solvent. The zone of growth activity appeared at R_F 0·9, corresponding very closely to the indolyl acetic acid marker at R_F 0·89. The evidence from the R_F values of the banana auxin in the various solvents mentioned provides evidence that it is either indolyl acetic acid or an indole compound very closely allied to it.

The nature of the unknown compound which gave the pink colour with perchloric acid was of interest, particularly as the R_F behaviour was similar to indolyl acetic acid in two different solvents, one of which is commonly used for the separation of the acidic auxins.

Simmonds[3] has shown that leucoanthocyanidins are present in banana fruits. It was found that the unknown compound, after spraying with 10 per cent hydrochloric acid in butanol, gave a pink colour on heating but not in the cold. Furthermore, on spraying with vanillin/hydrochloric acid (1 gm. vanillin dissolved in 15 ml. of concentrated hydrochloric acid + 35 ml. butanol), a pink colour was developed without heating. The hydrochloric acid and the vanillin reactions, modified from a method described by Bate-Smith[4], are together indicative that the compound responsible for the colour reactions is almost certainly a leucoanthocyanin. Although straight-growth promoting activity is not associated with the leucoanthocyanins, it is very possible that if a range of both temperate and tropical fruits is examined for indolyl compounds by paper chromatography and straight-growth bio-assay, confusing colour reactions with conventional chemical sprays may be found in the presence of mobile leucoanthocyanins.

Root Diffusates of *Solanum tuberosum* and *Digitalis purpurea*

THE hatching factor of the potato root eelworm has been shown to possess certain affinities with the cardiac glycosides[1] due, presumably, to the unsaturated lactone ring it is thought to contain[2]. The factor is contained in diffusates from the roots of growing potato plants[3]; but it has recently been shown that it can also be obtained from their leaves[4]. On the other hand, although the presence of cardiac substances in the leaves of the foxglove has been known for centuries, diffusates from their roots do not appear to have been examined: I have now found that such solutions have many of the properties of the potato root diffusates.

(1) Perfusion of the isolated frog heart shows that both potato and foxglove root diffusates possess cardiotonic activity.

(2) Colorimetric assay with either alkaline picric acid or 3,5 dinitro benzoic acid, methods used for cardiac glycosides[5,6], give reasonable agreement with heart assay. (In the case of the potato root diffusate, the colorimetric methods show promise for assessing hatching activity, as will be shown in full elsewhere.) With the benzoic acid reagent, both diffusates give an absorption peak at λ 385–390 mμ as shown in Fig. 1; digitoxin also gives this peak, which, so far as I am aware, has hitherto not been recorded: but it, and *Digitalis* tinctures, give other peaks too, not shown by the diffusates.

(3) Proctor *et al.*[7] have recently shown that digitoxin behaves as a peroxide in solution: solutions of both diffusates show peroxide activity after concentration in a Towers's evaporator. In the case of potato root diffusate the treated solution is relatively at least as active in stimulating hatching as the original.

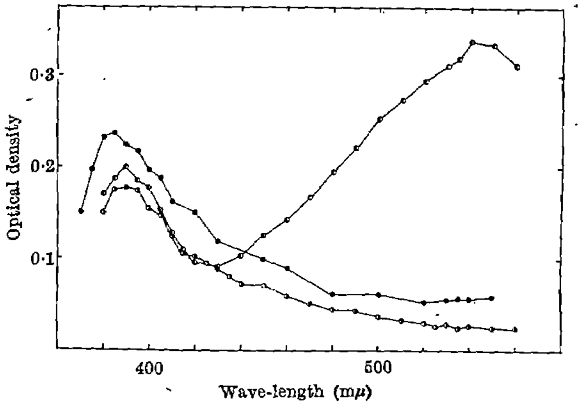

Fig. 1. 3,5 Dinitro benzoic acid reagent, and potato root diffusate (●), foxglove root diffusate (◑), and digitoxin (◐)

The diffusates probably contain a variety of substances, so that any conclusion must necessarily be provisional; moreover, none of the above points is critical evidence on its own. But, collectively, and together with the chemical evidence of Todd and his colleagues for the possible lactone structure of the hatching factor[2], the evidence is all consistent with the view that the two diffusates contain substances which have a chemical affinity with each other and with the cardiac glycosides.

Cardiac glycosides have been shown to influence sodium–potassium transport[8–11], and this property has also been demonstrated to be possessed by simpler lactones[12]. We have no direct evidence, as yet, that the hatching factor has this capacity, but, judging from the influence of ions on its activity, this does not appear to be unlikely. If this is so, one wonders whether the production of substances of this sort by plant roots may not be connected with the transport of ions by the roots themselves.

I am grateful for the tolerance and help of my chemical colleagues and for the facilities they have placed at my disposal. A grant from the Nuffield Foundation is gratefully acknowledged.

Immune Reactions to *Trichostrongylus colubriformis* Infestation in Sheep

In infestation of sheep with *Trichostrongylus colubriformis* both the intake of larvæ and infestation with adult worms stimulate the production of antibodies. These can be detected by means of a complement fixation test with an antigen prepared from ground larvæ[1].

During studies on the immune reactions of sheep to infestation with *T. colubriformis* it was found that after challenge of infested sheep with a further dose of larvæ, the body-weights of some remained static, or even declined, although the fæcal worm-egg count was virtually negative and the serum titre remained at a high level. Several such sheep were slaughtered and although very numerous adult *T. colubriformis* were recovered from the small intestine, few eggs were present in the females. In one case, from which approximately 20,000 worms were recovered, the serum titre had risen to 1/40 three weeks after challenge with 20,000 larvæ and remained at 1/40 or 1/80 until the lamb was slaughtered nine weeks later. During this period the worm-egg count never exceeded 400 per gm. fæces.

Further experiments revealed that the worms had reached maturity in the normal time, but that the females produced very few eggs. It was apparent that, in these cases, there is a suppression of egg-production associated with a sustained high serum titre, and that the worm-egg count is not then a reliable indication of the degree of infestation. A similar phenomenon has been noted by Roberts[2] in infestations of cattle with *Haemonchus placei*.

Dependence on Light of the Reversible Uptake of Inorganic Phosphate by *Hydrodictyon*

In the colony-forming green alga, *Hydrodictyon reticulatum*, uptake and metabolism of phosphate have been followed up by ordinary analytical methods (fractionation by the conventional trichloracetic acid technique, determination of phosphates with a modified procedure of Fiske and Subbarow[1]). The predominant feature in the changes of the phosphate fractions during a long-term culture with intermittent illumination (12 hr. light : 12 hr. darkness) is a marked increase in the large cells of the alga of the inorganic phosphate-level during the time of illumination. A comparable light-dependent accumulation of ions has been reported for other objects (reviewed by Brauner[2]), most recently for chloride by van Lookeren-Campagne[3]. In the case of *Hydrodictyon*, however, the accumulation of inorganic phosphorus in the light is reversible[4], since the low level of intracellular phosphate is completely restored during the dark time. This is shown in Fig. 1. The changes of the inorganic phosphorus have been found in the cells and, at the same time, in the surrounding nutrient solution. The differences in the phosphorus-level are not directly induced by *p*H changes in the medium.

Photosynthetically active red and blue light is more effective in phosphate accumulation than is green light of equal energy (Schott glass filters). Absence of carbon dioxide prevents the light-dependent accumulation almost completely. Persistent high

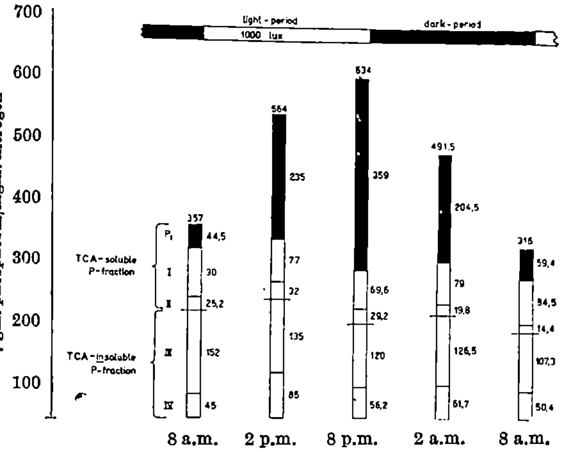

Fig. 1. Changes of phosphate fractions dependent on intermittent illumination of *Hydrodictyon*, based on total nitrogen (Kjeldahl). P_i, inorganic orthophosphate; I, stable phosphates soluble in trichloracetic acid; II, unstable phosphates soluble in trichloracetic acid (7 min.); III, unstable phosphates soluble in trichloracetic acid (7 min.); IV, stable phosphates insoluble in trichloracetic acid. Complete nutrient medium, 20° C.

levels of inorganic phosphorus can be obtained by shortening the darkness times versus times of illumination, and especially by continuation of the latter. These conditions are unfavourable for the vegetative development of the alga. The accumulation of inorganic phosphorus cannot be considered an obligatory ingredient or consequence of photosynthetic activity. This follows from the fact that low light intensities (for example, 300 lux), much below photosynthetic saturation but above compensation of respiration, are inactive in phosphate accumulation. The latter appears from about 1,000 lux on, where photosynthesis is beyond its linear dependence on light intensity. Thus we assume that phosphate accumulation and maintenance in the cell will be only exhibited at the expense of a certain surplus amount of energy available additional to the requirement of the photosynthetic mechanism proper.

Apart from the shifting of the inorganic phosphorus-level, reversible or irreversible changes in the different phosphate fractions of the algal cells during times of darkness and illumination are comparatively small, so far as they can be observed by usual analytical methods. The questions concerned will be discussed elsewhere[5]. Here it must suffice to say that polyphosphates, distributed between the fractions respectively soluble and insoluble in trichloracetic acid, can be increased by long illumination without additional carbon dioxide[6]. On the other hand, we did not obtain any evidence for an effective formation and utilization of polyphosphates in the balance of energy of the cells during changes in illumination and darkness and in the course of photosynthetic periodicity[7]. Labile phosphates of all kinds seem to be especially sensitive toward a lowering of the external supply of phosphorus.

This work was aided by the Deutsche Forschungsgemeinschaft.

Effect of Stereoisomeric Tartrates on Root Elongation in *Lepidium*

It was shown by Tetjurew[1] that free organic acids, especially malic and citric acids, exert an inhibitory effect upon seed germination.

Evenari[2] is of opinion that the inhibition by organic acids is not caused by the hydrogen-ion concentration alone, but that "it is mainly by their intrinsic natures as specific acids that they are inhibitors". This view is supported by the results of some experiments reported here, demonstrating the specific influence of different stereoisomeric forms of tartaric acid upon early stages of root elongation in cress (*Lepidium sativum* L.).

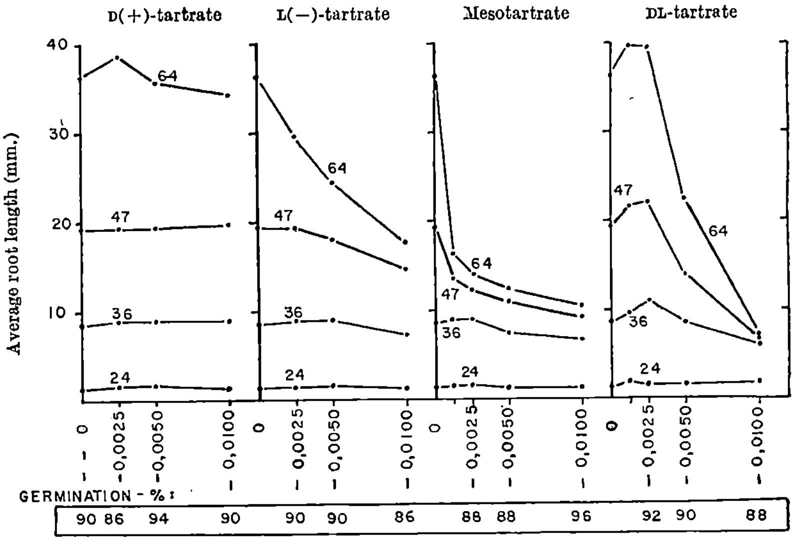

Fig. 1. Length of cress roots after 24, 36, 47 and 64 hr. in various concentrations of the different stereoisomeric tartrates. Abscissa: concentration of tartrate, moles per litre. Each point on the figure represents the average of fifty seeds. The seeds were harvested in 1955 and tested in December 1957. Below: germination percentages after 64 hr. in the different solutions

The technique was as follows. The different tartaric acids, analytical grades, were obtained from A. G. Fluka, Switzerland. As a precaution against microbiological contamination and chemical decomposition, the test solutions were made up the day they were to be used.

The seeds were germinated in Petri dishes on six layers of filter paper moistened with 10 ml. of neutralized tartaric acid. The initial *p*H value of the solution was adjusted to 6·0–7·0 by the addition of sodium hydroxide. No buffer was used. Twenty-five seeds were placed in each Petri dish and the dishes were placed in a dark-room at 21·5 ± 0·5° C.

The lengths of roots were measured to the nearest mm. The results were expressed as germination percentages and average length of root, disregarding ungerminated seeds. The latter were considered only for the calculation of the germination percentages. This procedure was chosen because certain treatments, such as irradiation by light of various wave-lengths (unpublished results), seem to influence only the germination percentage, the average length of root of those seedlings that did develop being unaffected. Other treatments, such as the addition of tartaric acids as described below, seem to influence only the average root-length and not the germination percentage.

The three stereoisomeric tartrates and the racemic DL-tartrate proved to have quite different and specific effects on the elongation of cress roots (Fig. 1).

D(+)-*tartrate*, the naturally occurring isomer, has no inhibitory effect at the concentrations tested.

L(−)-*tartrate* has little or no inhibitory effect during the first 36 hr. of germination. After 47 hr. L(−)-tartrate shows some inhibitory effect, and at 64 hr. the inhibition is considerable.

Mesotartrate is inhibitory from 36 hr. and onwards, and consistently more inhibitory than L(−)-tartrate.

DL-*tartrate*, which is the racemic mixture of D(+)-tartrate and L(−)-tartrate, was slightly stimulatory at low concentrations. At higher concentrations, it proved, unexpectedly, to be more inhibitory than the L(−) form given alone, and at the highest concentration even more inhibitory than the mesotartrate.

These effects might be related either to the metabolism of natural organic acids in the plant or to the action of growth substances, or to both. A discussion of the results must, however, be postponed until further evidence has been obtained.

'Recurrence' of *Macroderma gigas* Dobson

It is now fifty-eight years since E. R. Waite[1] employed the above title to record what he believed to be the second specimen of this bat, remarkable alike for being the largest member of the suborder Microchiroptera, for its carnivorous habits and for grotesque appearance. Waite's specimen came from the Pilbarra district of the North Western Division of Western Australia, 1,600 miles from the locus of Dobson's type, and provided an enormous extension of range; but he overlooked the fact that the species had been obtained in the Macdonnell Ranges of Central Australia in 1890 and again in 1894.

Since Waite wrote, a belief in the great rarity of the species and its near extinction has grown and has been fostered in popular writing by dwelling upon the abundance of its mummies in caves of the arid north of South Australia. These relics, however, are probably in large part sub-fossil, and recent field work has tended to show that the living animal is much more numerous and widespread than was believed. Tate[2] in 1948 obtained a series at Johansen's Caves near Rockhampton in coastal Queensland, near Olsen's Caves which had yielded it twenty years before, and Douglas[3], Robinson[4] and Ride, W. D. L. (personal communication), have shown that it persists in at least three localities in the North West and West Kimberley Divisions of Western Australia. I am now able to add three new sites in the Northern Territory: (1) the tableland scarp in the Macallum Creek area at about lat. 13° 16′ S. and long. 130° 44′ E.; (2) caves on the Field River near the eastern edge of the Arunta desert at about lat. 23° 34′ S. and long. 137° 53′ E.; (3) the Ellery Creek gorge in the James Range at about lat. 24° 5′ S. and long. 132° 49′ E. In addition numerous reports from intermediate localities of 'white flying foxes' drowned in tanks or otherwise destroyed are strongly suggestive of *Macroderma*.

It has been claimed that the chief food of the species consists of smaller bats. I have obtained no new evidence of this from personal observation, and the accounts of the aborigines are conflicting. In some parts of the country they regard this bat with aversion and state that men have been attacked by it on entering its roosts.

The Central Australian material is in close agreement with the type as described and with the desiccated material from South Australian caves; but it may be noted that the general pallor which has earned it the modern vernacular term 'ghost bat' is not an invariable feature. I have examined Queensland specimens in which the dorsal pelage is a deep brownish drab (about Ridgway's 'hair brown') and the ventrum a decided plumbeous in place of snowy white and with a corresponding darkening of integument; the cranial characters are normal.

A Chimæra of *Alaria* and *Laminaria* found in Nature

A CHIMÆRA of two kelps belonging respectively to *Alaria* and *Laminaria* was recently collected by one of us (M. I.) on May 18, from among a mass of seaweed which drifted ashore in the neighbourhood of the Marine Laboratory for Biological Education, Hokkaido Gakugei (Arts and Science) University, situated at Shirikishinai Village, Oshima Province, in Hokkaido. The frond of this chimæra is formed by the complete lengthwise and lateral adhesion of two half-fronds each representing one of the two quite distinct genera of Laminariales.

Our specimen, unfortunately, has lost its stipe and holdfast; it is 197 cm. in length and 13·7 cm. in width at the broadest portion. The frond is strongly curved inwardly along the margin of the *Laminaria* portion, thus indicating that this portion is markedly inferior in rate of frond-growth in length as compared with the *Alaria* portion. This latter portion is provided with a complete smooth midrib, up to 15 mm. wide and up to 3 mm. thick, and a complete lateral half of the membranous frond, up to 8·5 cm. wide and up to about 0·5 mm. thick, which is sprinkled with cryptostomata. Hairs emerging from the cryptostomata are densely infested with colonies of *Licmophora lyngbyei* (Kütz.) Grunn. In the lower part of the specimen the midrib of the *Alaria* portion coalesces directly with the *Laminaria* portion, whereas in the upper part it is separated from the latter by a narrow membrane representing the other lateral half of the *Alaria* frond (Fig. 1). On the other hand, the *Laminaria* portion is rather narrow—up to 5 cm. wide—and its upper half is reduced to a few scattered remnants attached along the margin of the *Alaria* portion. The *Laminaria* portion is nearly as thick as a normal frond of *Laminaria* growing at the same locality (up to 3 mm. thick near the outer margin where the frond is thickest). It is worth mentioning that the transition from the thin *Alaria* portion to the thick *Laminaria* portion is so smooth that the latter shows a very gradual increase in thickness in a transverse section through the border between the membranous part belonging to *Alaria* and the coriaceous part belonging to *Laminaria*. The zoosporangial sori are borne on both surfaces in the upper part of the *Laminaria* portion near the border between the two parts, in longitudinal narrow patches, 0·1–2·0 cm. broad (Fig. 1). After a further examination of several other characters, the constituents of this chimæra are concluded to be referable respectively to *Alaria crassifolia* Kjellm. and *Laminaria angustata* Kjellm.

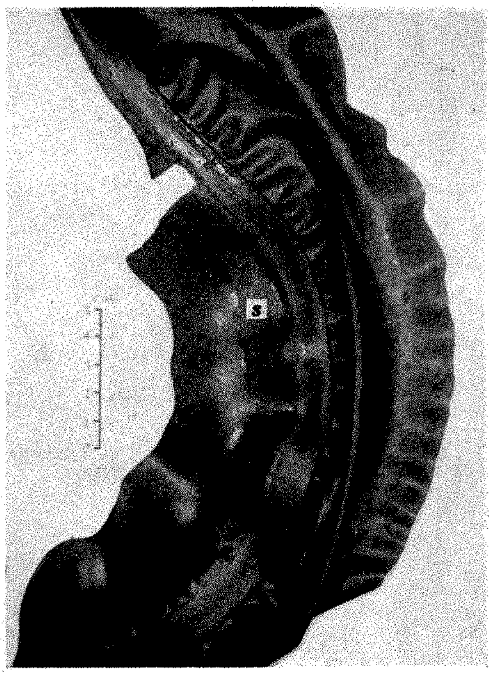

Fig. 1. Middle portion of the specimen showing a zoosporangial sorus (*S*) on the *Laminaria* portion

This sort of chimæra derived from two different genera of kelps has hitherto been unknown to science, so far as we are aware. On the other hand, two examples of malformation in *Laminaria* probably due to coalescence of fronds between two individuals of one and the same species have lately been reported from Hokkaido[1]. The origin of the chimæra reported here may be attributable to the lateral coalescence of two postembryonal plants at their damaged margins of the transition zone between the stipe and the frond, where the meristematic tissue for growth in length is situated in both the genera concerned, as in all Laminariales.

Zoospore Morphology of the California Strain of *Plasmopara viticola*

ZOOSPORES were obtained from the sporangia of the California strain[1,2] of *Plasmopara viticola* (B. and C.) Berl. and De T. growing in *Vitis californica* Benth. and *V. girdiana* Munson leaves. Germination occurred in distilled water at 10°–16° C. Active suspensions of zoospores were fixed by exposure for 30 sec. to the vapour of a 2 per cent osmic acid solution. Fixation darkened the flagella and permitted them to be measured easily under the light microscope. For electron microscopy the zoospore suspension was fixed, as above, on a 'Parlodion' film covering a 200-mesh electron microscope screen and allowed to dry.

Table 1. MEASUREMENTS of *Plasmopara viticola* (CALIFORNIA STRAIN) ZOOSPORES

Zoospore body		Flagella	
Length (μ)	Width (μ)	Long (μ)	Short (μ)
10·3	8·6	20·6	12·0
12·0	10·3	17·2	*
10·3	8·6	20·6	*
13·8	8·6	20·6	10·3
12·0	10·3	15·5	8·6
12·0	10·3	20·6	12·0
Mean 11·7	9·5	19·2	10·7

* Too curled to measure

Measurements of the zoospore body and flagella are listed in Table 1. The short flagellum tended to remain coiled whereas the long flagellum remained extended (Fig. 1*a*). Electron micrographs showed cilia of about 1μ in length on the short flagellum (Fig. 1*b*), but never any on the long flagellum. In both flagella long parallel strands of more dense

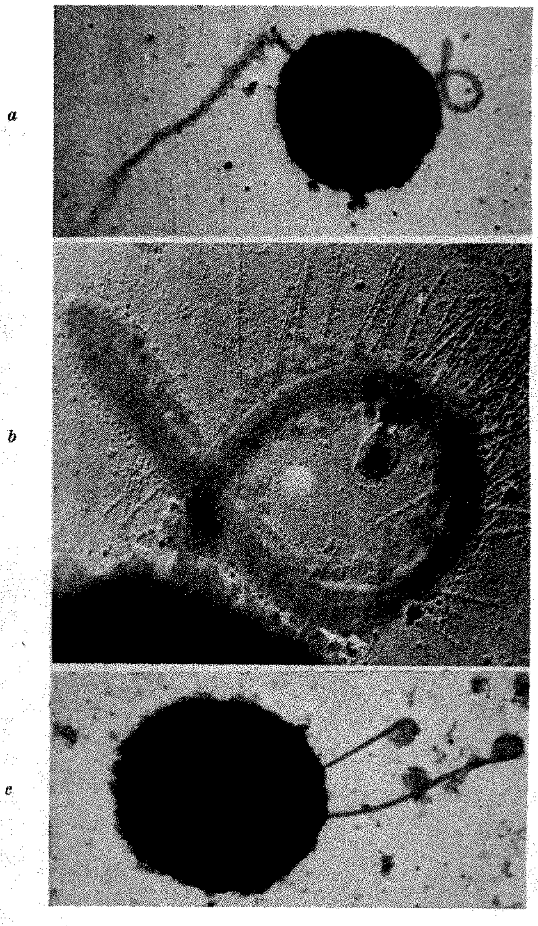

Fig. 1. Electron micrographs of *Plasmopara viticola* (California strain) zoospores and flagella. *a*, Zoospore with long and short flagella. Shadowed with uranium (× 2,030); *b*, short flagellum of *a* at higher magnification showing cilia; shadowed with uranium (× *c*. 14,060); *c*, zoospore with retracting flagella showing terminal 'knobs'; unshadowed (× *c*. 2,200)

material enclosed in a less dense matrix were present (Fig. 1*b*).

The mean dimensions of the zoospore body (Table 1) are similar to those illustrated by Arens[3] for *P. viticola* (13μ × 9·4μ). The inequality in the length of the two flagella has been noted[3,4]; but no figures have been published giving their relative dimensions. In most cases where they have been illustrated no marked difference in their lengths has been shown[4]. The one exception is Arens[3], who illustrates a long flagellum of 41μ and a short one of 26μ. The mean ratio of long to short flagellum, 1·79, is considerably greater than that for Arens's zoospore, 1·58. Lack of comparative data does not allow the attachment of any taxonomic significance to the relative length of the two flagella; however, this may be of importance.

The presence of the whiplash and tinsel-type flagella is one of the chief morphological features of the biflagellate series of the Phycomycetes[5]. The possession of these flagellar types by the California strain of *P. viticola* is the first reported for the Peronosporaceae and brings this family into conformity with the lower Peronosporales[6,7].

Zoospores with retracting flagella seen under the electron microscope (Fig. 1*c*) show that the swellings at the ends of the flagella are not the result of coiling as was reported for *Phytophthora infestans*[7]. Even though the long flagellum has retracted to half its normal length, there is no more than a portion of a loop of the dense flagellar core in the terminal swelling or 'knob'. Apparently, as the flagellum retracts the dense internal structure disintegrates and the disorganized material collects in the enlarging swelling.

I wish to thank Dr. Herbert Gold, of the Department of Plant Pathology, University of California, Berkeley, where this work was done, for help with the electron microscopy.

Behavioural Changes in Animals after Intracisternal Injection with Adrenocorticotrophic Hormone and Melanocyte-Stimulating Hormone

A FEW pharmacodynamic effects of adrenocorticotrophic hormone do not stem from its adrenocorticotropic properties[1,2]. The crisis of muscular hypertonus (acts of stretching) observed in dogs, cats, rabbits and rats injected intracisternally with small doses of this hormone are probably another example of pharmacological effects independent of its adrenocorticotropic properties. Although the behavioural changes following the intracisternal injection of many other hormonal preparations were investigated, the modification of muscular tonus mentioned above is obtained only with small doses of adrenocorticotrophic hormone or melanocyte-stimulating hormone. The term intracisternal injection indicates the replacement of liquor drawn from the cisterna magna with saline in which the various drugs under investigation are dissolved. The volume of these injections never exceeded 2 ml. in dogs, 1 ml. in cats and rabbits and 0·1 ml. in rats. The pH of the injected solutions was made as close as possible to physiological values.

Table 1. STRETCHING CRISIS FOLLOWING INTRACISTERNAL INJECTION INTO DOGS

Substance	Source	Dose	Animals with stretching crisis/treated animals
Adrenocorticotrophic hormone	*a*	0·12 I.U./kgm.	26/26

Sources: (*a*) Cibacthen Ciba; (*b*) beef preparation 732179 *A* Armour (5 × 10^8 U./gm.); (*c*) Armour, lot 369–766, no adrenocorticotrophic hormone activity; (*d*) Ambinon Organon; (*e*) Postipofiaan Richter; (*f*) Horm; (*g*) Vister; (*h*) Allen and Hanburys.

From Table 1 it can be seen that in the dog these two hormones were the only ones to induce the peculiar crisis of increasing muscular tonus spreading to many different muscular groups and resulting in a generalized act of stretching. In the dog the stretching crisis, illustrated in Fig. 1, appears within 1–2 hr. after the intracisternal injections as a recurrent series with intermissions of complete recovery and normal muscular tonus. 4–5 hr. after the injection not only does the crisis persist but the time between subsequent stretching acts becomes shorter and shorter so that the onset of one overlaps the end of the preceding one. This lasts for 24 hr. and more, ending with complete recovery. This phenomenon appears strictly dependent on the method of administration, for the infusion of comparatively large amounts of melanocyte-stimulating hormone (1 mgm./kgm.) into the common carotid artery is ineffective.

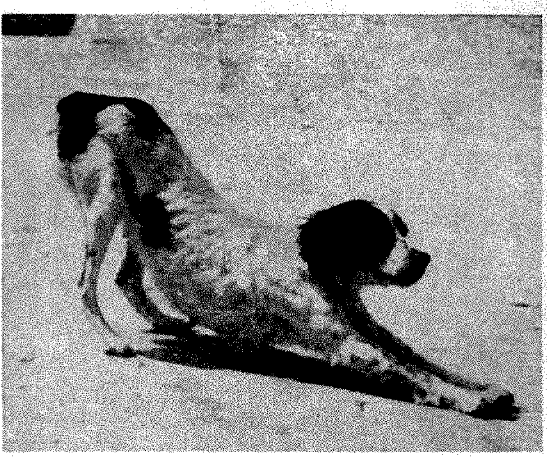

Fig. 1. Typical stretching crisis in a dog intracisternally injected with melanocyte-stimulating hormone

Stretching crises may also be seen in cats, rabbits and rats under the same conditions. However, a few characteristics may help in differentiating the symptoms caused by the two hormones in different animal species. When melanocyte-stimulating hormone is injected into the cisterna magna of rabbits a short period of convulsions precedes a state of catatonic-like stupor. Within 1 hr. the latter is interrupted by a stretching crisis often accompanied by yawning. A complete recovery occurs within 4–5 hr. Catatonic-like stupor occurs in rats, together with scratching movements of unusually long duration. In cats the stretching crisis follows a period of either drowsiness or catatonic-like stupor. Other symptoms may be associated with the intracisternal injection of these two hormones. It is important to mention that neither rectal temperature (in rabbits) nor blood-reducing substances (in dogs) vary. In dogs eosinopænia and ptyalism and in rabbits a slight arterial hypotension may occur.

The liquor drawn while the behavioural changes are in progress does not cause either the isolated guinea pig ileum or the isolated rat uterus to contract. Nevertheless the same liquor if injected intracisternally to another dog evokes the symptoms described above. In the latter case the latent period is not shortened as one would expect. The latent period lasts longer after injecting either hormone into the lumbar subaracnoidal space of dogs, but the symptoms remain unchanged.

Since in dogs adrenalectomy does not curtail the muscular hypertonus caused by intracisternally injected adrenocorticotrophic hormone, this effect cannot be due to its adrenocorticotropic activities. Moreover in dogs the intracisternal injection of a number of drugs causing eosinopænia (histamine, 0·1 ; 48/80, 1 ; serotonin creatine sulphate, 0·1 ; 1-epinephrine, 0·02 ; 1-ephedrine, 2 ; *d*-amphetamine, 1 ; mgm./kgm.) is not followed by behavioural changes similar to those described above. Finally, chlorpromazine and reserpine injected into the cisterna magna of dogs do not evoke a stretching crisis.

The possible explanations of the mechanism of this pharmacological activity of adrenocorticotrophic hormone and melanocyte-stimulating hormone lack experimental support. Nevertheless as a working hypothesis I suggest that the polypeptide chain common to both hormones is either directly or indirectly involved.

Induction of Melanin Patterns and of Hardening as Separate Processes in the Cuticle of Albino Locusts with Internally Absorbed Phenol Substrates

THE cuticle of the albino strain of *Schistocerca gregaria* is more or less colourless because of a complete absence of melanin and apparent utilization of a phenol substrate in the hardening process which does not give rise to a coloured scleroprotein.

When protocatechuic acid was added to the hæmolymph, the extra-embryonic liquid system, or the yolk system of an albino, it was significant that it did not give rise to a coloured quinone–protein substance. On the other hand, dihydroxyphenylalanine and catechol did. These two latter phenol substances, however, failed to do so when phenylthiourea, a blocking agent of tyrosinase, was also added.

In view of a phenolase enzyme being present in the albinos, it seemed likely, therefore, that the introduction of different phenol substrates into their hæmolymph and tissues might lead to changes in the cuticle. Injection techniques, however, incur numerous disadvantages[1-4], and in this case they would be liable to invalidate at once any results that might be obtained.

An immersion technique was therefore carried out as follows. The wax layer of the epicuticle of the last few segments of the abdomen of albino nymphs was first removed by rubbing it off with cotton wool soaked in chloroform. An albino thus treated (from now on referred to as a 'dewaxed' albino) was then placed in a ring of 'Plasticine' fixed to the rim of a test tube so that the dewaxed end of its abdomen was dipped below the surface of the phenolic solution to be tested. Solutions of tyrosine, catechol, dihydroxyphenylalanine and protocatechuic acid of $N/20$ strength were used. Controls consisted of using albinos with their wax coating untouched and 'dewaxed' albinos either dipped in saline, or simply suspended in air. The test albinos were kept in position for periods ranging from 24 to 48 hr.

'Dewaxed' albinos dipped in catechol or tyrosine, as just described, developed a pattern of brown to black pigment in their cuticles. This pigment could not be removed with acid–methanol, ethyl alcohol or acid-ethanol, which showed it to be melanin[5]. Catechol, however, was responsible for a far more intense and extensive pattern than tyrosine. This pattern first developed in the dorsal region and posterior margins of the cuticular plates of the abdomen ; it then spread forward to the thorax and the head and the colour slowly intensified. Moreover, the pattern laid down resembled that of the normal strain of the same insect. The controls remained unaltered, and from this it is evident that when the 'dewaxed' albinos are suspended in a phenol solution with only the dewaxed end of the abdomen below the surface, the phenol substance passes through the dewaxed cuticle of the end of the abdomen into the hæmolymph and tissues and forward to the head region where the melanin pattern is relatively well developed.

When solutions of protocatechuic acid and dihydroxyphenylalanine were used, melanin was not deposited in the albino cuticle. In the light of other work[6], this is surprising in the case of dihydroxyphenylalanine. An examination of sections of the cuticles of albinos treated with these two substances, however, revealed that extra hardening had taken place ; the outer region of the albino cuticle, normally colourless, had been tanned to an amber colour. When catechol was used, the melanin deposits were also confined to the outer region of the cuticle. It was most significant, however, that the catechol had not caused the cuticle to turn amber colour where melanin had not been deposited. Catechol, therefore, seemed to be exclusively concerned with melanization and protocatechuic acid and dihydroxyphenylalanine with sclerotization.

The results therefore show, first, that the immersion technique described demonstrates that phenol substrates originating in the hæmolymph and tissues of an insect must reach the outer region of the cuticle before they can be oxidized in the presence of an activated phenolase. Secondly, that melanization and hardening can be induced to take place as separate processes utilizing different substrates. Thirdly, that catechol is exclusively concerned with melanization, and protocatechuic acid and dihydroxyphenylalanine with sclerotization.

We are as yet uncertain why dihydroxyphenylananine was not also utilized for the formation of melanin, as it is supposed to do[6]. However, in view of the recent finding of catechol in insects[7], it is likely, on the basis of the results reported here, that it could be a natural substrate for melanization in insect cuticles.

Work on this problem is still in progress and it is hoped to publish a fuller account in due course.

Distant Hybrids from Parents with Reduced Immunological Reactivity

IF they hatch out at all, there is usually a high incidence of malformation in hybrids between guinea fowl hens and domestic fowl cocks[1-3]. Adult hybrids have been described only twice[4,5].

I wished to verify whether a distant cross of the above combination was favourably influenced by a decrease in the reciprocal immunological reactivity of both the parent birds. The results support this assumption, as I obtained four hybrids which have survived into maturity.

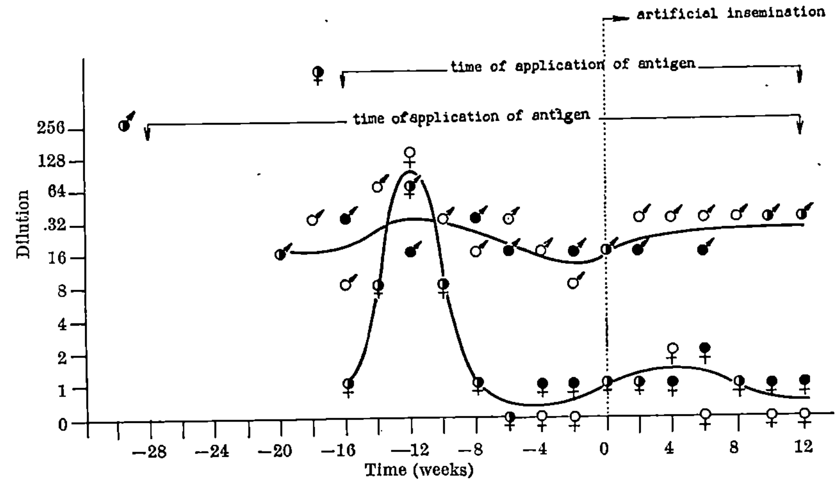

Fig. 1. Course of mean agglutinin titres in four parent birds in both experimental crossings

Procedures influencing the immunological reactivity of experimental animals (decrease of antibody production to erythrocytes of the other parent species—Fig. 1) and results of subsequent crossing using artificial insemination are compared in Table 1 with my own control results and those of other authors. The fertilization percentage in both experimental crossings far exceeds that of the control guinea fowls. Surprisingly, 4 of the 9 hybrids which hatched out have survived into maturity; they are now 14–16 months old.

In the control hens, as distinct from the experimental birds, the fertilization percentage displays a high degree of individual variability (11–74 per cent). In order to stabilize the frequency ratio n/N (n = number of fertilized eggs, N = number actually laid), the transformation of the random variate was used and Student's test was afterwards applied. Although the test cannot be regarded as absolutely conclusive in the present case, it nevertheless is almost significant at the 5 per cent level ($P < 0{\cdot}05$). It appears, therefore, that the results can be ascribed to the measures described above. In view of the high individual variability, a larger number of parent birds should be used in future work, and an attempt should be made to determine the cause of a high

* One of these two males is the same as that in the preceding cross.

fertilization percentage in some control guinea fowl hens.

In my view, even the negative results of Ryle and Simonsen[6] do not conflict with this working hypothesis. They investigated the possibilities of distant crossing (domestic hen and turkey cock and *vice versa*), as a criterion of immunological tolerance. In most of the birds, however, they tested immunological tolerance following the intra-embryonal injection of foreign blood by the immunity response of the inoculated birds. The provocation of immunity in weakly tolerant birds may, in my opinion, have had an unfavourable effect on distant crossing.

The histological examination of the gonads of four hybrids from both experimental crossing, which died during hatching or just before or afterwards, showed that all were males. The seminiferous tubules were normally developed, but did not contain spermatogonia, so that the hybrids would evidently have been sterile.

The serological analysis showed no hybrid substance[5,7] in our hybrids apart from the common and specific antigens for both parent species.

I thank Mr. V. Matoušek, of the Institute of Hygiene and Occupational Diseases, for carrying out the statistical analysis.

Environmental Conditioning of Flax

EXPERIMENTS carried out over a number of years have shown that remarkably large differences can be produced in the weight of flax plants as a result of the effect of the environment on previous generations of plants. In one experiment, all eight combinations of nitrogen, phosphorus and potassium fertilizer treatments were applied to forty plants of an inbred, self-fertilizing variety in the damp, dull season of 1954. The progeny, which were grown under a uniform set of fertilizer treatments, were cut at ground-level at maturity and weighed. The differences in the weights of the progeny (C_1 1955) due to the parental treatments are shown in Table 1. Some types are as much as two and three times the weights of others and, with the exception of the nitrogen plot, they are closely correlated with the weights produced by applying the fertilizers directly to the plants (Table 1, C_0 1955).

The differences were undiminished in the second generation grown in 1956 (C_2 1956), although the seed obtained from the first generation was of the highest quality in weight, appearance and germination, and the C_1/C_2 correlation was virtually complete ($r = 0{\cdot}97$). In another test on the second generation grown in 1956, 960 plants descended from plants receiving nitrogen and potassium two generations earlier weighed 0·85 cwt., and an equal number descended from plants receiving phosphorus and potassium weighed 2·63 cwt.—three times as much. The difference of 1·78 cwt. had a standard error of 4·1 lb. Again there was no difference in seed weight, germination capacity or energy, and the plants themselves within each type were highly uniform. Large differences have also been observed in the third generation and there is evidence from young plants that they occur in the fourth generation.

The experiment was repeated by applying the same set of fertilizers in the warm, sunny season of 1955, but this time the effect on the progeny grown in 1956 was much less (Table 1, C_1 1956), although the differences were still significant and, apart from the nitrogen plot which was exceptional before, substantially the same. Evidently seasonal factors are as important as nutrition. This was also demonstrated by another experiment in which plants from seed collected in 1955 were, for comparable fertilizer treatments, twice the weight of plants from seed collected in 1956, when the two sets of plants were grown together in 1957.

Table 1. WEIGHT IN LB. OF EIGHTY PLANTS. $s.D. \times t$ = LEAST SIGNIFICANT DIFFERENCE FOR $P = 0{\cdot}05$

	NPK	NP	NK	N	PK	P	K	Nil	$s.D.\times t$
C_0 1955	11·4	11·8	4·4	6·1	9·6	10·4	8·9	7·3	3·3
C_1 1955	11·1	9·5	3·7	12·1	11·3	8·4	7·8	5·9	1·2
C_2 1956	17·5	15·9	6·5	18·7	15·5	14·2	12·4	8·1	3·3
C_1 1956	11·6	9·2	8·2	7·8	10·9	9·3	8·2	8·2	2·2

The inheritance of such large differences to at least the fourth generation is likely to be due to cytoplasmic change rather than to maternal effects, and this is supported by other experiments. (i) Plants were grown from seed from capsules collected at varying stages of ripeness. Plant weight increased logarithmically with decrease in seed weight to the limit where the seed was so small that no germination occurred. (ii) Forty plants of two conditioned types which were reciprocally grafted retained their identity in both stock and scion. (iii) Reciprocal crosses between two conditioned types resembled the female parents more than the male, but there was also clear evidence of transference of effect through the pollen in both directions. (iv) The conditioned types do not produce the same relative dry weights when grown in the field in the summer as in a warm greenhouse under the lower light intensity and shorter day of winter. Presumably the types are adapted to different environments.

One of several reasonable hypotheses which can be put forward at this stage is that, with relatively high temperature and low light intensity, cell division can proceed rapidly; but the number of cytoplasmic self-duplicating particles falls, due to a shortage of photosynthetic products, the utilization of these products being also influenced by mineral supply. The altered cytoplasm stimulates the nucleus to synthesize different substances, or different amounts of the same substances, to establish a new equilibrium between nucleus and cytoplasm. The new equilibrium could be at least as stable as the old, and the new plant type to which it gives rise would have the appearance and constancy of a distinct genotype. Such a cytoplasmic – nuclear interaction may further simulate genetic change by the nuclei themselves having an effect on the difference between reciprocal crosses of environmentally conditioned types, the pollen nucleus complementing any small effect of the pollen cytoplasm. In short, plants may remain differentiated as a whole over several generations in addition to the normal differentiation of parts of plants within a generation. Temperature/light relations will probably play an important part in further investigations.

A detailed account of these studies on flax, and on other organisms, will appear in due course. This work was aided by a grant from the Agricultural Research Council.

'Purple Pericarp' : a Monofactorial Dominant in Tetraploid Wheats

A number of varieties of tetraploid wheats originating from Abyssinia have purple- or violet-coloured grains, due to the presence of an anthocyanin in the cells of the pericarp. As part of a programme of hybridizations undertaken for the production of tester stocks carrying useful marker genes, a white-grained eligulate variety of *Triticum durum* Desf. (from Cyprus) was crossed with a purple grained variety from Abyssinia, *T. durum* var. *arraseita* Hochst. (=*T. dicoccum* var. *arraseita* Perc.). Although the F_2 family raised was only small, it is felt that the results should be put on record because they indicate that the purple pericarp colour is inherited as a simple monofactorial dominant.

The F_1 plants, when allowed to mature normally (Table 1), bore purple grains like the male parent. Of 44 F_2 plants harvested, the ears of 28 bore purple grains, 12 ears had non-coloured grains and 4 could not be classified owing to discoloration, immaturity, etc., of their grains.

Table 1

Grains	Observed (O)	Calculated (C)	Deviation ($O - C$)	$\frac{(O - C)^2}{C}$
Purple	28	30	− 2	$0{\cdot}1\dot{3}$
Non-coloured	12	10	+ 2	0·40
Total	40	40	0	$0{\cdot}5\dot{3}$

With $\chi^2 = 0{\cdot}5\dot{3}$, for 1 degree of freedom, $P = 0{\cdot}5$–$0{\cdot}3$, showing a good agreement with a 3 : 1 ratio.

The only relevant report in the literature appears to be that of Caporn[1], who studied the progeny of a cross *T. polonicum* × *T. durum* var. *arraseita* ('*T. eloboni*') made by Biffen. In this case the F_2 consisted of 28 plants with fully purple grains, 8 with the colour restricted to longitudinal streaks and 136 with non-coloured grains. In the F_3, some of the non-coloured grained plants gave streaked grained plants and non-coloured grained ones.

Although Caporn's puzzling results may perhaps be due to the introduction of additional factors affecting pericarp colour from the *T. polonicum* parent, it is felt much more likely that the streaked and impure non-coloured grained plants resulted from a shading effect of the closely investing long glumes caused by the *polonicum* gene or genes. In support of this possibility, it should be mentioned that although the ears of the F_1 plants of the present cross normally bear purple grains as noted above, it was observed that if the ears are enclosed in black paper while maturing, only non-coloured grains are produced.

Hence, in the light of the results now presented, and despite the observations of Caporn, it is suggested that the purple pericarp colour occurring in Abyssinian tetraploid wheats is inherited as a monofactorial dominant character.

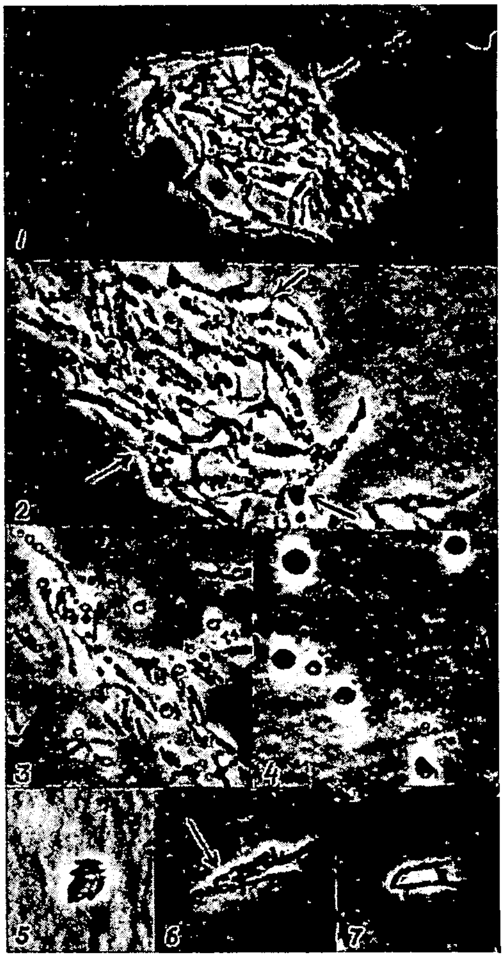
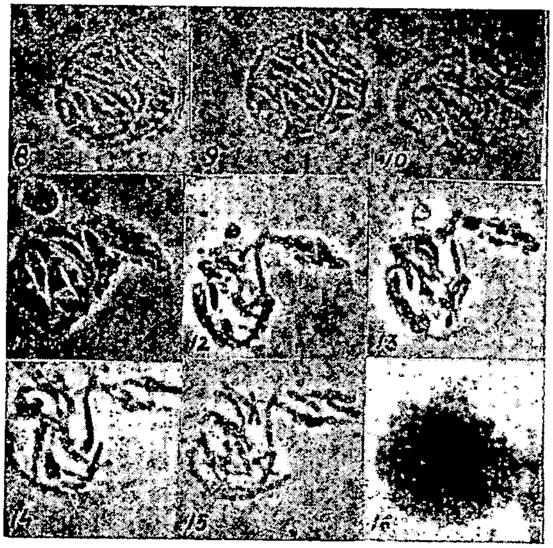
Atypical Forms of Tubercle Bacilli (Strain *B.C.G.*)

Atypical forms (granules, globules, spore-like bodies) of *M. tuberculosis* have been observed by many investigators since Koch's time[1-9]. In the present investigation the *B.C.G.* strain of *M. tuberculosis* grown on 'Tween'-agar blocks was studied by means of the light- and phase-contrast microscope.

Many of the bacilli multiplied by simple transverse fission. Some, however, branched into filaments. Granules appeared in these forms : in some instances a sufficient number of granules appeared to fill the entire rod (Fig. 1). The granules increased in size. Some which measured 0·2μ in diameter when first seen were 1–3μ or more in diameter (Fig. 2). Other



Figs. 1–7. Phase-contrast photographs. (× 1,400)



Figs. 8–15. Serial photographs of a developmental process over a period of 70 days. At the beginning, 8, 9 and 11 were taken in a bright field. 16, photograph of a hydrochloric acid/fuchsin stained smear. (× 1,400)

granules looked like empty rings and resembled spores (Fig. 3). Besides angular bodies arising from the fusion of single rods (Fig. 5), a considerable number of free globules could be observed (Fig. 4), more or less similar to large bodies or protoplasts of Enterobacteriaceae[10–11], and also protoplasts of aerobic spore-forming bacteria[12].

It was considered important that granules and globules of different sizes may arise from the conjugation of two or more individual rods (see arrows in Figs. 2, 6). Conjugation of rods without the subsequent formation of globular bodies, as previously described[9], was also observed (Fig. 7).

In some instances the 'large bodies' could be seen to break into rods (Figs. 8–15). Although this alone would point to their abundance in nuclear material, the application of different nuclear staining methods seems to confirm this point (Fig. 16).

The assumption that in the process of fusion of different rods into large bodies, genetic material might be assembled, and that their breaking up into rods would result in a redistribution of this material, makes further investigations necessary.

We are indebted to Dr. S. Vas, McGill-Montreal General Hospital Research Institute, for his valuable advice in microphotography.

Strain Sensitivity of Albino Rats to Reserpine

During work on the effects of reserpine on chromaffin tissue, it became apparent that albino rats of Sprague–Dawley and Wistar strains differed markedly in their sensitivity to reserpine. This phenomenon has been investigated by observing the loss of catechol amines by the adrenal medulla in response to intravenous injections of 1, 5, 10 and 15 mgm./kgm. of the drug.

Male rats weighing 200–250 gm. (Wistar) or 250–300 gm. (Sprague–Dawley) were used in groups of 8 or 10. 24 hr. after an injection of reserpine the animals were killed by a blow on the head. The adrenal glands of two animals were fixed after bisection in either formol–dichromate (neutral formalin 10 per cent, potassium dichromate 3 per cent) or potassium iodate followed by 10 per cent formalin[1]. Dichromate-fixed material was embedded in paraffin wax and sectioned at 6μ. Material treated with iodate was sectioned at 35μ on the freezing microtome. Some sections were examined unstained, others were counterstained with either hæmatoxylin or sudan black. The remaining adrenal glands obtained from each group of animals were pooled and weighed: pressor amines were extracted[2], purified on alumina[3], and assayed by the method of Euler and Hamberg[4].

The results are summarized in Tables 1 and 2. A positive chromaffin reaction is given by cells which contain either adrenaline or noradrenaline while a positive iodate reaction is only given by noradrenaline-containing cells[5]. In the present work the results obtained by assay correlate well with the histochemical findings. 5 mgm./kgm. of reserpine administered to Sprague–Dawley strain animals produces the same degree of depletion of medullary catechol amines (almost complete) and the same constitutional disturbances as does 15 mgm./kgm. given to Wistar rats. Doses of 10 mgm./kgm. and more given to Sprague–Dawley animals result in convulsions and death. Constitutional disturbances include drowsiness, lachrymation and diarrhoea.

The degree of catechol amine depletion is dependent upon the dose of reserpine employed. In partially depleted glands the relative proportions of adrenaline

,,	10	*G*+ or *P*+	–
,,	15	– or *P*+	–

G, Generalized reaction; *P*, patchy reaction.

Table 2

Rats	Reserpine (mgm./kgm.)	Total catechol amine		Noradrenaline (per cent)	Depletion (per cent)
		μgm per gm./adrenal	μgm. per rat		
Sprague–Dawley	0	946	42·0	18	—
,,	1	321	15·0	15	64
,,	5	35	1·5	—	96
Wistar	0	872	28·0	15	—
,,	1	411	21·5	16	23
,,	5	146	8·0	—	71
,,	15	42	1·4	—	95

and noradrenaline remain normal, noradrenaline forming about 16 per cent of the total amine, and there is no evidence of a selective loss of either amine such as occurs in association with insulin hypoglycæmia. Insufficient pressor amine was extracted from glands after injections of 5 mgm./kgm. and more to allow an estimate of the individual amines.

It should be noted that glands removed 24 hr. after an injection of reserpine show an increase in weight as compared with controls. This change is due to cortical hypertrophy and is associated with an increase in the esterase content of the inner part of the zona fasciculata and the zona reticularis. As a result of this change, the adrenals show an abnormally low content of pressor amines if these are given as per gm. of adrenal weight, and it is therefore preferable to give the catechol amine content per rat (providing rats of uniform age and weight are used), or per unit body-weight.

I would like to express my thanks to Ciba Laboratories, Ltd., for supplies of reserpine ('Serpasil').

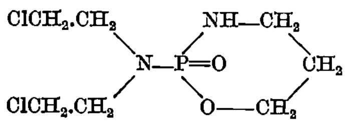
Chemotherapeutic Action of a Cyclic Nitrogen Mustard Phosphamide Ester (B 518-ASTA) in Experimental Tumours of the Rat

THE synthesis of new cytostatic drugs is governed by the attempt to find new substances which unite maximum therapeutic effectiveness with minimum toxicity. For this purpose it seems to be advantageous not to apply the substance in its active form, but by introducing suitable chemical groups to transform it into an inert transport substance which will be reconverted into the active form at the site of therapeutic action in the body. This principle has already proved of value in the treatment of prostatic carcinoma with stilbœstrol diphosphate[1].

Using the same method, Friedman and Seligman[2] combined the active *bis*-(β-chlorethyl)amino-group with phosphoric acid. The resulting compounds proved, however, to be therapeutically ineffective. In our experiments we allowed *bis*-β-chlorethyl-phosphamide-dichloride to react with alkanolamines. Thus we obtained cyclic *bis*-(β-chlorethyl)-phosphamide esters with two phosphamide bonds and one ester bond. Chemical analysis has shown that the basicity of the phosphamide nitrogen and thus also the reactivity of the chlorine atoms are considerably reduced. In comparison with *bis*-(β-chlorethyl)amine (nitrogen mustard, HN2), the rate of chlorine ion liberation in aqueous solution (at 37° C.) is considerably lowered.

The examination of the therapeutic effectiveness of numerous homologous compounds in different graft tumours of the rat has shown B 518-ASTA to be particularly effective and well tolerated. B 518 is the experimental designation of the cyclic propanol-amido-ester of *bis*-(β-chlorethyl)-phosphamide. Its trade name is 'Endoxan R', Asta-Werke A.G., Brackwede (Germany).



The minimum lethal dose of B 518 in the rat is 160 mgm./kgm., whereas for N-oxide mustard the minimum lethal dose is only 50 mgm./kgm., and for nitrogen mustard even as low as 1·5 mgm./kgm. Thus the toxicity of B 518 is remarkably low.

In therapeutic trials on fully developed tumours of the rat, for example, the solid Yoshida sarcoma (20 gm.), Walker–256-carcinoma (1 gm.) and Jensen sarcoma (5 gm.) we obtained a definite cure with a single intravenous injection of B 518. The medium effective dose (*DC*50) was found to be 3·9 mgm./kgm. for the Yoshida sarcoma, 6·0 mgm./kgm. for the Walker carcinoma and 3·6 mgm./kgm. for the Jensen sarcoma, that is, it amounts to only 2–4 per cent of the minimum lethal dose. Thus the therapeutic index of B 518 is more than twice as wide as that of N-oxide mustard and about 10 times as large as that of the ethylenimines such as TEM, TSPA and *E* 39-BAYER. In addition, B 518 proved to be the only substance which considerably inhibited the DS-carcino-sarcoma previously resistant to all other compounds[3].

In vitro tests, in which B 518 was incubated with tumour cells at 37° C., showed complete inertness of the compound up to a concentration of 10^{-3} gm./ml., the cells being then grafted on to healthy young rats and their taking capacity checked. This makes it appear probable that the cyclic propanol amide ester of *bis*-(β-chlorethyl)-phosphamide actually represents an inert transport form, from which the highly active form is liberated only within the body.

The results will be published more fully in further papers[4].

'Compensatory Hyper-regeneration' in the Antennæ of Hemiptera

WOLSKY[1] claims that prior to his 1957 demonstration, under the above title, there was no experimental evidence to show that the antennal oligomery frequently encountered in Hemiptera Heteroptera results from the unusual course regeneration takes after larval injury. But in 1829 Heineken[2] amputated the antenna of a reduviid larva and obtained an adult exhibiting just those features which Wolsky now notes. Gäbler[3] studied antennal regeneration in three families of Heteroptera, and Balazuc[4], unaware of Gäbler's work, has given a full account of regeneration in a reduviid. In addition, the literature abounds with references to the field occurrence of both uni- and bi-lateral oligomery, more especially in Lygaeidae: in view of the work of Heineken and his successors there is no doubt that such cases are the result of larval injury. Consideration of the structure of the bug antenna, however, now suggests that analysis of the experimental results can be taken one stage further.

It has been pointed out that if amputation takes place sufficiently early in larval life then the adult antenna is shorter (and thicker) than normal because, while each 'segment' regenerates to a length greater than usual, there is always one 'segment' less than in the normal adult (except, of course, when only part of the distal 'segment' has been removed)[4]. Now consideration of the bug antenna shows it to comprise a basal scape, a pedicel (bi-annulate in Pentatomoidea) and a bi-annulate flagellum[5]. From the observations of earlier workers, including Wolsky, it is apparent that whereas a regenerated lygaeid or reduviid antenna has three 'segments', that of a pentatomoid has four: this suggests that in each case there is anarthrogenesis within the flagellum. As the articulation between flagellum and pedicel differs from other antennal articulations—the pedicel–flagellum articulation forms part of a proprioceptive organ—examination of oligomerous individuals and identification of the annuli presents no difficulties[5]: inspection of many oligomerous Lygaeidae and Pentatomoidea confirms that in every case there is but a single flagellar annulus.

It is concluded that when an antenna is amputated anywhere between the base and the intra-flagellum articulation, a bug larva will regenerate an antenna more or less shorter than normal—depending upon the time and instar at which amputation is carried out and upon its site—but always without forming an articulation within the flagellum. It follows that the factor responsible for arthrogenesis within the flagellum is dissociable from the factor controlling length of regeneration and is present only in the embryo (or is inhibited during regeneration).

Inaccuracies of Anaphase Estimation of Radiation-induced Chromosome Exchange

Wolff and Luippold[1] have demonstrated that analysis of metaphase aberrations and of anaphase bridge frequencies gives qualitatively different radiation-dose curves, and directed attention to discrepancies between various results that some have found difficult to accommodate in classical chromosome breakage theory. There seems to me to be a factor ignored in classical theory that may explain some of these discrepancies.

In classical theory, exchanges are produced in numbers proportional to the square of the X-ray dose. Breaks are produced in numbers proportional to dose. At a given dose, D, the probability of an exchange in any one chromosome arm will be αD^2 and the probability of a chromosome break in any chromosome arm will be βD. The probability of an exchange and a break involving the same chromosome arm will be $\alpha D^2 \times 2\beta D$, the factor 2 being introduced because the exchange involves two arms. Now half these coincident breaks will be between the exchange point and one of the centromeres and may effectively prevent an anaphase bridge occurring. The expected number of anaphase bridges will be proportional to $\alpha D^2 - \alpha B D^3$. Better algebra may no doubt be devised, but the essential point will remain that the larger dose will increase the probability that an exchange may be 'undone' by the production of a suitable break.

It seems unlikely that the resulting correction will explain the discrepancy observed by Wolff and Luippold unless the effective breaks adhere in metaphase and separate in anaphase. But it would explain discrepancies between metaphase and anaphase data for chromatid exchanges, and would require some departure from the $(\text{dose})^2$ law for exchanges at high doses.

Sex-linked and Sex-limited Mutation of the Fly *Muscina stabulans* (Fall.) (Muscidae)

In a series of papers, Tate[1-4] has described the inheritance and expression of a mutation, white-apricot (w), in the blowfly *Calliphora erythrocephala*. He showed that this factor is probably situated in the X-chromosome and is recessive to the dominant allele for wild-type eye colour which is located in the homologous section of the Y-chromosome in heterozygous males. No evidence was found of crossing-over between X- and Y-chromosomes in this fly. The object of the present communication is to report a similar case in the fly *Muscina stabulans*.

A few white-eyed females were noticed in a stock of *M. stabulans* which had been started with eggs of an unknown number of females from Johannesburg. The F_1 generation flies from these females were all of the wild-type, but in the F_2 generation white-eyed females again appeared. By breeding from the white-eyed females and males from the same batch, a pure line was eventually obtained in which the females are all white-eyed and the males all of the wild-type. This line has now been maintained for more than twelve generations without a single white-eyed male or red-eyed female appearing. A wild-type line was also selected for, and it has produced no white-eyed females in more than twelve generations.

When white-eyed females were crossed with wild-type males, the F_1 generation was wild-type, but the F_2 generation comprised 79 white-eyed females, 71 wild-type females and 169 wild-type males. When heterozygous wild-type males were crossed with homozygous wild-type females, the resulting F_1 and F_2 generations were both wild-type, but the F_3 generation yielded 43 white-eyed females, 239 wild-type females and 291 wild-type males. These figures support the hypothesis that, in this stock, the mutant gene (w) is situated in the X-chromosome and that there is a dominant allele (W) in the homologous section of the Y-chromosome ($\chi^2 = 1{\cdot}533$, $P > 0{\cdot}4$ and $\chi^2 = 2{\cdot}058$, $P > 0{\cdot}3$, respectively). Since the heterozygous and homozygous wild-type flies are phenotypically indistinguishable, and since there is no gradation in the expression of the mutant gene, the above explanation of the observed facts seems the most likely. The fact that no white-eyed males were found suggests that crossing-over between the centromere and (*w*) locus is at least very rare or wholly absent.

In the Calyptrata, besides the case of *Calliphora erythrocephala* reported by Tate, white-eyed mutants have been described in the blowflies *Lucilia cuprina*[5] and *Phormia regina*[6]; but in these cases the mutant genes are simple autosomal recessives to the dominant alleles determining wild-type eye colour. It would be interesting to have information on the location of eye colour genes in other members of the Calyptrata.

I am indebted to Dr. D. Nolte, of the Department of Zoology, University of the Witwatersrand, for reading this communication.

Niobium in Ascidians

IT has been known since 1911[1] that the blood of certain species of ascidians contains organically bound vanadium. Bertrand[2] has shown that most marine invertebrates contain between 0·2 and 2 parts per million of vanadium dry weight, whereas in ascidians the figure may be as high as 6,500 p.p.m. dry weight. This high level is not, however, true of all species, and in some families the level, where investigated, is not significantly above that found in other groups of marine invertebrates. *Didemnum candidum*, for example, is quoted as containing 2·6 p.p.m.

In the course of some other work I was led to the conclusion that some of these species of ascidians may possibly contain niobium in place of, or in addition to, vanadium. This has in fact proved to be correct. Preliminary analyses have kindly been made for me by the Chemical Research Laboratory of the Department of Scientific and Industrial Research, using spectrographic methods. These analyses have been supplemented by the use of chromatographic methods in the Plymouth Laboratory. By these methods the flesh of *Mytilus edulis* was shown to contain 0·22 p.p.m. of vanadium dry weight and less than 0·001 p.p.m. of niobium. *Phallusia mammillata* (a species of ascidian with known high vanadium content) had 1,260 p.p.m. of vanadium dry weight in the flesh (compared with 1,700 p.p.m. found by Webb[3]), while niobium was not detected (that is, less than 0·001 p.p.m. dry weight). In *Molgula manhattensis* both vanadium and niobium were detected. Expressed in p.p.m. dry weight, the vanadium content of the test of *Molgula* was 16, of the flesh without the test 101, and of the whole body 54 (compared with 31·8 given by Bertrand[2]); the niobium content of the test was 1·9, of the flesh without the test 56, and of the whole body 26·5. These figures were based on analyses carried out on pooled material from more than a hundred individuals. Investigations using niobium-95, however, suggested that only about one quarter of the individuals contained any niobium, the remainder lacking even the ability to ingest it. The chromatographic analysis of single individuals confirmed this: all individuals contained either vanadium or niobium, but there was no detectable niobium in animals which had significant vanadium, while only traces of vanadium could be detected in animals with detectable niobium. In the former group the vanadium content ranged from 29 to 98 p.p.m.; in the latter the vanadium content was less than 2 and the niobium content 25–75. The niobium appears to be organically bound.

If, as has been suggested, the vanadium present in petroleum deposits is derived from ascidians, it seems likely that these may also be the source of the niobium which is likewise present in these deposits.

Rearing Newts in the Laboratory for Experimental Purposes

I HAVE always considered the methods employed in the rearing of newts in the laboratory as too time-consuming. The newts are generally maintained in finger bowls; the water is usually changed once a day, and during the summer months a cool room is required, or the water is changed several times a day.

My aquarium was designed to eliminate these difficulties. It consists of a sheet metal tank 6 in. high and divided into compartments. Small holes are cut in the partitions so that the water can flow freely. A fine mesh screen is welded on the bottom of the partition so that the newts cannot crawl from one compartment to another. One end of the aquarium rests above a sink and the water is piped in at the opposite end. An overflow pipe regulates the level of the water at 3 in., and the diameter of the overflow pipe is at least twice that of the inflow pipe. A large pipe at bottom-level is used for draining the aquarium, which need be done only two or three times a year.

A free area 1½ in. wide is provided at each end of the tank by making the partition 3 in. less than the length of the tank. This prevents the newts escaping through the overflow or inflow pipes. The tank can also be drained without removing the newts. The inflow pipe enters the tank at about 4½ in., which is 1½ in. above the water-level, making it easy to observe the amount of water flow.

The compartments are 6 in. × 8 in., and there are 15 of them in the present model. Since the water flows constantly, more newts can be placed in each compartment than in a non-flow container of equal size. The largest number that have been reared in each compartment is twelve.

Each compartment contains a liberal supply of floating water plants, such as *Elodea* (*Anacharis*), *Lemna* (duckweed), *Riccia* and several snails. Five sections of clear glass cover the aquarium so that the plants receive adequate light. Since the glass is in sections, newts can be removed with long forceps from a compartment without uncovering more than three compartments. A screen covering tends to shade the plants, preventing them from thriving.

It has not been necessary to use biological water. Newts do equally well in tap water, and I have raised them in the city water of New York City and Chicago.

Most investigators who employ newts feed each one individually by offering it meat with a pair of forceps; this occupies considerable time. I find that if small pieces of ground muscle are placed in the water once a week the newts will eat readily; only 10–15 min. a week is then required to feed a hundred or more newts.

By employing the principles of the aquarium described above, many more newts can be studied at less expense of time and money than by the methods generally used.

Release of Phosphate from Soil Minerals by Hydrogen Sulphide

In this laboratory it was observed that some colonies of soil bacteria and fungi, grown on carrot-extract agar containing 0·1 per cent ferric phosphate in suspension, turned the particles of phosphate in their vicinity black. Blackening occurred only when hydrogen sulphide was produced by these organisms, some of which formed it anaerobically but others aerobically. Bromfield[1] showed that hydrogen sulphide was produced by several strains of *Bacillus megaterium* in apparently well-aerated soils. These results suggested that sulphides in soil may reduce ferric phosphate to black ferrous sulphide and release available phosphate.

The influence of 24-hr. treatment with hydrogen sulphide at room temperature was determined on phosphates of ferric iron (isomeric with metastrengite) of calcium (hydroxy apatite, octa phosphate and a trace of brushite) and of aluminium (amorphous by X-ray analysis), and also on ferric and calcium phytates.

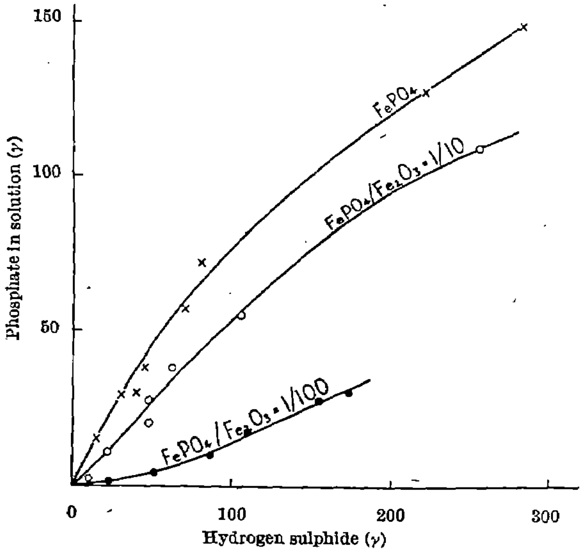

Fig. 1. Release of phosphate from ferric phosphate by hydrogen sulphide in the presence and absence of iron oxide

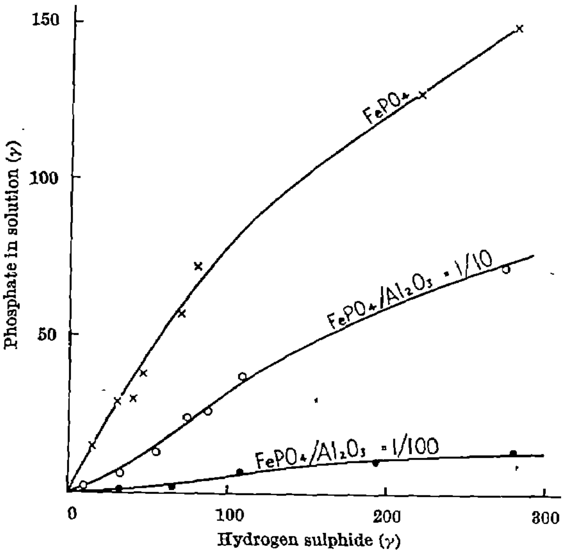

Fig. 2. Release of phosphate from ferric phosphate by hydrogen sulphide in the presence and absence of aluminium oxide

Phosphate was released from ferric phosphate by much lower concentrations of hydrogen sulphide than from tri-calcium and aluminium phosphates or from ferric and calcium phosphates. It was considered that most soils would not contain sufficient hydrogen sulphide even under anaerobic conditions to attack any phosphate other than ferric phosphate. Since most soils contain sesquioxides which might compete with ferric phosphate for any hydrogen sulphide formed, additional treatments were included to test the effect of hydrogen sulphide on ferric phosphate mixed with either iron oxide (hæmatite) or aluminium oxide (boehmite) in the ratios of 1 : 10 and 1 : 100.

Increasing amounts of sulphide increased the quantity of phosphate in solution, measured colorimetrically[2] as shown in Figs. 1 and 2.

At all sulphide-levels the amount of phosphate in solution was suppressed when sesquioxides were present, particularly by the finely crystalline aluminium oxide, but less so by the coarser iron oxide. The level of phosphate in solution reached a maximum after several hours and thereafter fell steadily, suggesting refixing of phosphate on the surface of sesquioxide particles.

Sesquioxide would greatly hinder release of phosphate, but in waterlogged siliceous soils, low in sesquioxides but high in hydrogen sulphide, release of phosphate might be of importance.

I thank Dr. R. J. Swaby for helpful suggestions during this work.

FORTHCOMING EVENTS

Monday, March 31

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Informal Evening on "Future Radiocommunication Methods for Civil Aircraft". Talk by Mr. W. E. Brunt.

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. A. H. Toms: "Soil in British Railway Civil Engineering".

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. G. Wilkinson: "Transitional Metal–Hydrogen Complex Compounds".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. Thor Heyerdahl: "The Enigma of Easter Island".

Tuesday, April 1

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 10 a.m. and 2.45 p.m.—Dr. G. W. H. Gardner, Mr. A. D. Baxter and Mr. L. H. Bedford: "Rockets and Guided Flight" (Leonardo da Vinci Lectures).

Institute of Refrigeration (joint meeting with the Low Temperature Group of the Physical Society, at the Junior Institution of Engineers, Pepys House, 14 Rochester Row, London, S.W.1), at 5.30 p.m.—Dr. G. G. Haselden and Dr. L. Klimek: "An Experimental Study of the Use of Mixed Refrigerants for Obtaining Cooling Over a Temperature Range".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Sir Claude Inglis and Mr. F. J. T. Kestner: "The Long-Term Effect of Training Walls in Estuaries".

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m. Discussion on "Economic Aspects of Electrical Engineering".

Tuesday, April 1—Wednesday, April 2

Institute of Biology (in the Beveridge Hall, Senate House, University of London, Malet Street, London, W.C.1), at 10 a.m. daily—Second International Symposium on "Freezing and Drying".

National Coal Board (at the Mining Research Establishment, Worton Hall, Worton Road, Isleworth, Middlesex)—Conference on "The Mechanical Properties of Non-Metallic Brittle Materials".

Wednesday, April 2

Physical Society, Colour Group (in the Physics Department, Imperial College, Imperial Institute Road, London, S.W.7), at 9.45 a.m.—Eighteenth Annual General Meeting.

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Prof. C. W. Allen: "Solar Radiation" (Symons Memorial Lecture).

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Dr. A. Klinkenberg (N.V. De Bataafsche Petroleum Mij.): "Electrostatics and Explosion Hazards in the Petroleum Industry".

Society for Analytical Chemistry (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Meeting on "Gas Chromatography".

Thursday, April 3

Institute of Metals, London Local Section (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Annual General Meeting, followed by Mr. W. E. Ballard: "New Protective Coatings for Metals".

Saturday, April 5

British Interplanetary Society (in the Tudor Room, Caxton Hall, Caxton Street, London, S.W.1), at 6 p.m.—Mr. F. R. F. Taylor: "Problems of Handling Large Missiles".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (male, with sound practical and teaching experience) in Crop Husbandry—The Principal, Institute of Agriculture and Horticulture, Oaklands, St. Albans, Herts (April 4).

Assistant, Grade B (with a good honours degree and preferably teaching experience), in Chemistry, to teach general chemistry to G.C.E. Advanced Level and assist with teaching of inorganic chemistry at degree level—The Principal, Brighton Technical College, Brighton (April 5).

Lecturer in Physical Chemistry, and an Assistant Lecturer (Grade B) in Chemistry—The Registrar, College of Technology, Portsmouth (April 5).

Spectroscopist (with an honours degree and/or the A.R.I.C., and a knowledge of, and a special interest in spectroscopy) in the Public Analyst's Section of the Public Health Department—The Registrar, The University, Bristol (April 8).

Assistant Director of the Royal Botanic Gardens, Kew—Civil Service Commission, 30 Old Burlington Street, London, W.1, quoting Ref. S.4825/58 (April 10).

Lyons Fellow (graduate in medicine or science (if the latter preferably with a Ph.D. in one of the medical sciences)) for Multiple Sclerosis and Allied Nervous Diseases, to take part in a combined programme of research, under the direction of the Professor of Pathology, on the biology of myelin and the experimental pathology of the demyelinating diseases—The Registrar, The University, Leeds 2 (April 14).

Senior Lecturer in Mathematics—The Secretary, Royal College of Science and Technology, Glasgow (April 14).

University Demonstrator in Physical Chemistry—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge (April 16).

Senior Lecturer (with high academic qualifications and/or professional qualifications, and some teaching experience) in Chemical Engineering at Neath Technical College—The Director of Education, County Hall, Cardiff (April 17).

Assistant Lecturer in Pharmacology—The Registrar, The University, Manchester (April 19).

Bacteriologist (with a university honours degree in science or equivalent qualifications together with some research experience and a knowledge of, and experience in, general bacteriology) in the Division of Fisheries and Oceanography, Commonwealth Scientific and Industrial Research Organization, Cronulla, near Sydney, New South Wales, Australia, to study the importance of bacteria in building up and decomposing organic matter and in metabolizing the various inorganic compounds present in the sea—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 320/137 (April 19).

Graduate (preferably with some postgraduate experience in microscopy and/or biology), for work involving applications of ultraviolet and interference microscopy, etc., in biology—The Secretary, Chester Beatty Research Institute, Fulham Road, London, S.W.3, quoting "EMFR" (April 19).

Senior Lecturer (university graduate with industrial and teaching experience, and preferably some experience in development work in a branch of electronics) in Applied Physics—The Principal, Twickenham Technical College, Egerton Road, Twickenham, Mddx (April 19).

Chair of Physics—The Registrar, University College of Wales, Aberystwyth (April 30).

Chief Laboratory Steward (preferably with university or equivalent experience) in the Department of Chemistry, University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 30).

Imperial Chemical Industries Research Fellows in Chemistry, Physics and allied subjects, for example, Pharmacology, Engineering or Metallurgy—The Registrar, The University, Manchester 13 (April 30).

Research Assistant or Junior Fellow in Aeronautical Engineering—The Registrar and Secretary, The University, Bristol (April 30).

Research Fellow in the Department of Nuclear Physics, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 30).

Lecturer or Assistant (Grade B) (with teaching and research experience) in Geology (Palæontology and Stratigraphy) up to the standard of the B.Sc. (Special) degree of the University of London—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (May 3).

Assistant (with an appropriate honours degree) in Research in Agricultural Botany, for research on crop plant evolution—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (May 16).

Assistant Professor (preferably with a Ph.D. in a biological subject and experience in electron microscopy) of Anatomy at Dalhousie University, Canada—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Canada, May 31).

Chair of Medicine—The Registrar, The University, Manchester 13 (May 31).

Assistant (Grade B) to teach Physics—The Principal, College of Technology, Queen Street South, Huddersfield.

Physical Chemist (with a first- or second-class honours degree in chemistry or equivalent, experience of handling radioactive isotopes, all types of counting equipment, and a knowledge of electronics) at the Chemical Research Laboratory, D.S.I.R., Teddington, to lead a small team engaged in radiometric work—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.207/8A.

Physicist or Engineer, to co-operate in the design and development of a large liquid hydrogen bubble chamber and associated plant for use in high energy nuclear physics research (Ref. No. 220(*a*)); and a Draughtsman, to work with the above (Ref. No. 220(*b*))—The Registrar, The University, Liverpool 3, stating the appropriate Ref. No.

Postdoctoral and Predoctoral Research Associates in Experimental and Theoretical Chemical Physics in the Molecular Excitation Group—Dr. R. W. Nicholls, Department of Physics, University of Western Ontario, London, Ontario, Canada.

Qualified Technician or Junior Technician (male or female) in the Pathological Laboratory—The Secretary, Wembley Hospital, Wembley, Middlesex.

Research Assistant (honours graduate in microbiology or zoology) in the Vaccine Lymph Department, for work on the development of tissue culture methods in the bulk production of virus and related viral techniques—The Secretary, The Lister Institute, Elstree, Hertfordshire.

Scientific Assistant (Abstractor) (with a degree in agriculture or natural science and a knowledge of languages)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Maidenhead, Berkshire.

Scientific Assistant (with a good science degree, a reading knowledge of two European languages (preferably other than French or

German), ability to write good English and preferably a knowledge of soil science and plant physiology), for work in a scientific information service involving abstracting and indexing—The Director, Commonwealth Bureau of Soils, Rothamsted Experimental Station, Harpenden, Herts.

Scientist (preferably with a pass degree or at least H.S.C. (science) or equivalent, and an interest in a wide range of scientific subjects), to assist in the planning and operational control of overseas trials, and to collaborate with authors in the preparation and editing of reports from scientific records obtained during trials, the post involves tours of duty abroad—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. 1732/34.

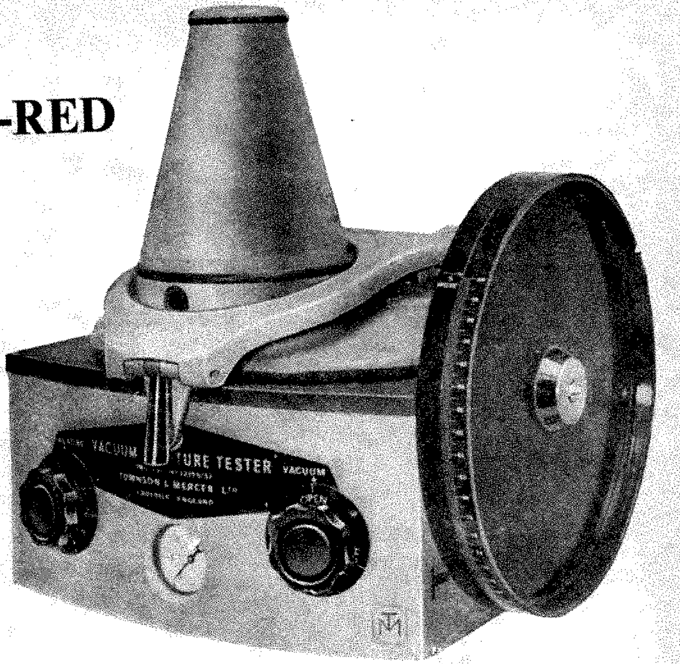
Another T. & M. Invention

THE VACUUM INFRA-RED MOISTURE TESTER

(Provisional Patent No. 12198/57)



Direct reading of percentage (0–100% in 0·2% divisions).

Very low temperature of sample (therefore suitable for antibiotics, etc.).

Very quick results. (Cotton, wet sand, synthetic fibres—two to three minutes.)

Very robust enclosed mechanism. (Operated by all-comers for ten days without adjustment ! ! !)

This is not a cheap instrument, but it will enable many industries to get quick and very accurate results on their products in a way never before possible

(AS THE SAMPLE IS WEIGHED IN VACUO DURING DRYING, THERE IS NO RE-ABSORPTION OR AIR CURRENT ERROR AS IN NORMAL MOISTURE TESTS.)

TOWNSON & MERCER LIMITED

CROYDON *Telephone*: THOrnton Heath 6262 ENGLAND

NOW AVAILABLE

95% NITROGEN 15 ISOTOPE

Standard Forms: – Nitric acid, nitrates, ammonium salts, potassium phthalimide, nitric oxide, nitrogen dioxide, nitrogen, ammonia

Exclusive distributor in Great Britain:

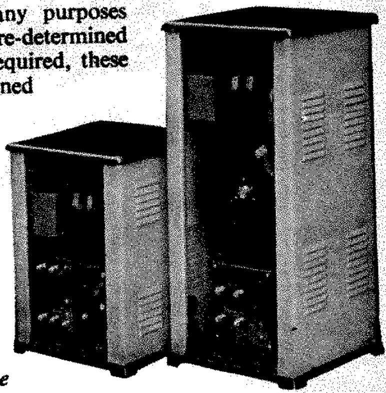
ZENITH
(REGD. TRADE-MARK)

Automatic VOLTAGE REGULATORS *with Electronic Control*



Essential for many purposes where a constant pre-determined supply voltage is required, these Regulators are designed to give a controlled output voltage within 1% with input voltage variations up to plus or minus 10%. Manufactured for single- and three-phase loads from 5 up to 23 kVA per phase.

Illustrated brochure free on request.

Facts to hand!

- **UNFAILING VACUUM PLU PRESSURE SERVICE**
- **EXTREMELY ROBUST**
- **QUIETLY EFFICIENT**
- **GIVES A LIFETIME OF DOUBLE SERVICE**

These are the facts which industry has established for the 'SPEEDIVAC' COMBINED VACUUM PUMP AND COMPRESSOR and endorses them by the steady number of *repeat* orders placed with us.

VACUUM: 20–28 ins Hg (250-40·0 mm. Hg)
PRESSURE: 10–15 lb. sq. in. (0·7–1·0 kg. sq. cm.)

TEXTBOOK OF MEDICAL TREATMENT
Seventh Edition. Edited by D. M. DUNLOP, M.D., F.R.C.P., SIR STANLEY DAVIDSON, M.D., F.R.C.P., and S. ALSTEAD, M.D., F.R.C.P., P.R.F.P.S.G.
944 pages 33 illustrations 55s.

In active preparation

STAPHYLOCOCCUS PYOGENES IN RELATION TO MEDICINE
By S. D. ELEK, M.D., Ph.D., D.P.H.
About 900 pages. Fully illustrated.

TEVIOT PLACE, EDINBURGH

GRIFFIN
ESTABLISHED IN 1820

SAMPLING METHODS FOR CENSUSES AND SURVEYS
FRANK YATES, Sc.D., F.R.S.

For all concerned with the presentation and handling of statistical data, and of interest to the mathematical statistician. "*A notable addition to the growing literature on the theory and practice of statistical methods.*"—Nature.

2nd Edition, revised and enlarged. 400 pages. Many tables. **Price 42s net**

ANALYSIS OF DRUGS AND CHEMICALS
NORMAN EVERS, Ph.D., F.R.I.C.
and
WILFRED SMITH, B.Sc., F.R.I.C.

This book includes monographs of a large number of new substances which are increasingly used in medical practice, food manufacture, agriculture, and in many branches of chemical industry. A valuable supplement to the British Pharmacopœia and Codex.

546 pages. *Very fully indexed.* **Price 60s net**

PRESERVATION OF THE COUNTRYSIDE

A PASSAGE in the report of the Nature Conservancy for the year ended September 30, 1957, discussed the effects on the Conservancy's work of the plans announced towards the end of 1956 for the development of Milford Haven as a major port, capable of taking large oil tankers. The proposals under consideration include an oil refinery on the north side of the Haven and a depot for trans-shipping iron ore from Canada at Angle on the southern side, and there is also a plan to erect a barrage across the River Cleddau. The shores of Milford Haven at its seaward end are in the Pembrokeshire Coast National Park, and nearly three-quarters of the proposed development would be located in the Park. The Haven and the area surrounding it also contain a flora and fauna of considerable scientific interest; and the national nature reserves of Skomer, Skokholm, Grassholm and Flimston Stacks and Cliffs and the sites of special scientific interest at Crabhall Saltings, Dale Point, Sleekstone and Goulthrop Roads, Marloes Sands and Westdale Bay, and Broomhill Burrows may be affected, directly or indirectly, by the proposed developments.

The main threats are the greater disturbance and development arising from an influx of industrial population into previously remote and sparsely inhabited places, the risk of oil and other forms of pollution arising from the increased seagoing traffic and industrial development and the deterioration, or even worse, of scientific interest due to gravel winning, or the deposition of material near Dale Point and Crabhall Saltings. Other problems will inevitably arise from the increase in population and secondary industrial and commercial activities required to support the proposed development which, so far as the Conservancy's interests are concerned, come immediately from those proposed by the Esso Petroleum Co., Ltd., and the British Petroleum Co., Ltd., and by the Milford Docks Co. The companies have given firm assurances that they will do all that is reasonable and within their power to eliminate the risk of oil pollution, or minimize its effects should it occur, and the Nature Conservancy intends to press for the strict enforcement of the Oil in Navigable Waters Act, 1955, which provides the necessary statutory protection, and of the International Convention for the Prevention of Pollution of the Sea by Oil, 1954; and the Conservancy trusts that the oil companies which are authorized to develop sites in Milford Haven will, in concluding charter parties for vessels of countries which are not parties to the Convention, include a clause stipulating no discharge of oil into the sea within 500 miles of Milford Haven. The companies have also agreed to consult the Conservancy before depositing dredged material in any area likely to affect the sites of special scientific interest in the Haven.

An immediate threat has arisen in the proposal to win gravel by dredging in Dale Bay; but following consultation with the Ministry of Transport and Civil Aviation, the Haverfordwest Rural District Council and the development company, agreement has been reached on the issue to the company of a temporary lease for obtaining gravel, subject to certain conditions as to area and amount. It is hoped that fuller information will become available in the course of the development about any possible effect on the sites of special scientific interest, and that by further consultation this can be eliminated or minimized, and surveys have been undertaken to record the present coastal vegetation before any changes take place.

The eighth report of the National Parks Commission, which has since been issued (see p. 950 of this issue), also considers the proposed developments at Milford Haven at some length, though the Commission equally expresses profound misgivings as to the invasion of the Snowdonia National Park by the proposed nuclear power station at Trawsfynydd. It is indeed the scale and nature of such developments that lead the Commission to the uncompromising general conclusion to its report, namely, that such development is wholly alien to the very purpose of national parks, which is the preservation of the distinctive rural character of fine landscape for the enjoyment and recreation of both present and future generations.

The Commission holds that the siting of large-scale industry in national parks should be sanctioned only on over-riding and inescapable national necessity, and after alternative sites outside the national park areas have been zealously sought. In the absence of such proved national need, there is no justification for sacrifice of the essential character of unspoilt country, which is itself a real, if intangible, national need. A countryside once invaded by industry in this way is irretrievably altered in character, and its value for agriculture and for recreation is damaged or for ever destroyed. So important is this value of unspoilt country to a crowded and urbanized island like Britain that we must recognize before it is too late that we are trustees for future generations, and that we can only at our peril disregard that trust.

That general principle is of vital importance in considering the Milford Haven Conservancy Bill*, which was published last December, and also the Commission's approach to the main proposals affecting the Pembrokeshire Coast National Park and other particular developments. In moving the second reading of the Bill in the House of Commons on November 22, the Minister of Transport and Civil Aviation, Mr. H. Watkinson, was concerned essentially with the practical purposes of the Bill, which establishes a conservancy authority for Milford Haven to be known as the Milford Haven Conservancy Board. Reference was made to a section of the Bill which would require the Board, in considering any proposals, to have regard to the desirability of preserving natural beauty; conserving flora, fauna and geological or physiographical features of special interest; and of ensuring an easy passage at all times through the waters of the Haven for ascending salmon and sea-trout. But it was left to other speakers, notably Mr. Ness Edwards, Mr. P. Williams and Mr. D. Donnelly, to point out that the way development was handled under the Act would apply the decisive test as to whether the Government has a real concern for the national parks, and to stress the outstanding importance of the amenity issue.

---

* Milford Haven Conservancy Bill. Pp. iv+38. (London: H.M. Stationery Office, 1957.) 1s. 9d. net.

Mr. A. Neave, the Joint Parliamentary Secretary to the Ministry, in replying to the debate, readily responded, pointing out that there are further safeguards in that clauses would restrain the Board from depositing dredged materials so as to prejudice establishment of the Pembrokeshire coastal path; and making the Board subject to the provisions in the Town and Country Planning Act, 1947, would provide a further safeguard for amenities. Similarly, by constituting the Board as a harbour authority under the Oil in Navigable Waters Act, the area would be safeguarded against the danger of oil pollution. Nevertheless, there is need for great vigilance. It would have been more reassuring had the Government sponsors of the Bill directed attention spontaneously to the significance of these features of the Bill. Reference might have been made to the Electricity Act, 1957, Section 37 of which empowers the Electricity Generating Board, any Area Board, the Electricity Council and the Minister to have regard to the desirability of preserving natural beauty, conserving flora, fauna and geological or physiographical features of special interest, and of protecting buildings and other objects of architectural or historical interest, and to take account of the effect of any proposals on these objects. As the Nature Conservancy points out in its annual report, such clauses have removed the danger that legal or financial action required to make desirable and fair arrangements may prove *ultra vires*. The National Parks Commission also expresses satisfaction that this and other new and more satisfactory provisions relating to the holding of public inquiries, while not resolving the problems of the ever-increasing conflict between the claims of industrial development and that less tangible national asset, an unspoilt countryside, have given statutory recognition to the importance of this aspect of planning.

Nevertheless, the National Parks Commission is seriously concerned at the effect of industrialization on the scale contemplated at Milford Haven on the national park area. Some two-thirds of a 900-acre site for the Esso Petroleum Co. jetty and oil refinery would be within the National Park. The Commission submitted at the public inquiry last July that the developers should be obliged to show beyond doubt that there is no other site available outside the National Park which would meet the material requirements.

As regards the proposals of the British Petroleum Co., while the Company has been concerned to minimize their effect on the landscape so far as it is able, the Commission is particularly concerned with the effect of the suggested form of tank. These tanks, 140 ft. in diameter and 60 ft. high, would be seen over a wide area as an incongruous element in the landscape, and although the Commission's recommendation that no tanks should be erected in a defined part of the area was not written into the proposals, the Pembrokeshire County Council, as local planning authority, was given control over the siting. Since the Bill received Royal Assent in July 1957 there have been discussions on the site on the best measures for making the tanks less obtrusive.

A third development at Milford Haven to which the National Parks Commission refers is that proposed by the Steel Company of Wales for building a jetty and establishing a stocking ground for iron ore at Chapel Bay on the south shore well within the Park. The Commission believes that this project would be totally at variance with any conception of the right use of land in a national park, and hopes that the Company will seek an alternative site elsewhere. That hope is unlikely to be fulfilled now that the Minister of Housing and Local Government has approved the oil refinery project. The other developments will almost inevitably follow, once it has been conceded that the incomparable advantages of the Haven for the very large tankers which are likely to carry much of our oil supplies in the near future constitute a national interest over-riding that of amenity even in a national park area; and it is of course such future and secondary developments, with the consequent profound changes in the whole character and appearance of the area, that are at the root of the Commission's objections.

That much conceded, whether rightly or wrongly, the utmost care should be taken to see that the destruction of amenity is kept to a minimum, and that positive action is taken to offset the inevitable loss of some natural beauty. The Milford Haven Conservancy Bill has left the House of Commons, but something could still be written into it to ensure that adequate means, such as a new town corporation, well financed and competent to handle all these developments and consequential changes, are available. It is unfair and unwise to place all the responsibility for planning and financial aspects on the local authority, even when it has proved itself as capable as the Pembrokeshire County Council of taking long views and seeking the national interest. It is already clear that the companies primarily concerned are willing and anxious to play their part, and the current annual reports of both the Nature Conservancy and the National Parks Commission testify as fully to what can be done by co-operation and with goodwill and public support as they do to Government parsimony in its refusal to provide the resources to make the National Parks Act effective. Indeed, the Dolphin Development and Management Co. has already offered to serve, without fee, as planning consultants to the Pembrokeshire County Council in collaboration with its planning officer and, through him, in liaison with the Ministry of Housing and Local Government.

This offer goes far to meet the most urgent need which follows from the Minister's approval of the project of the Esso Petroleum Co. Only something in the nature of a regional development corporation can prevent the worst effects of industrial development from repeating themselves in the area, and reconcile the conflicting demands on the use of the land which will arise from housing and social needs. Foresight as well as adequate financial resources are required, and the powers and resources of a small and sparsely populated county are hopelessly inadequate to deal with such a situation. Although it may prevent development in the wrong places, it cannot effectively induce development in the right places, even if it can tell where the right places are. Failure to place adequate resources at the disposal of the National Parks Commission has already undermined its work, and often prejudiced local authorities against it. Milford Haven provides a decisive test of the sincerity of the Government's support of the National Parks which no protestations of economy can evade; finance, in fact, is the crux of the situation.

At the public inquiry into the iron ore stocking proposal, the Pembrokeshire County Council and the National Parks Commission claimed that reasonable requirements of the Steel Company of Wales for a deep-water jetty and ore stocking ground in Milford Haven could be adequately met with less injury to the amenities of the National Park at Ferry Cwm, to the east of Bullwell. At this inquiry, however, the first under the new procedure adopted in accordance with recommendations of the Franks report, the Admiralty indicated that while it had no objections to the Chapel Bay site, it reserved the right to consider all the implications if any other site were seriously considered. The Admiralty claims were not disclosed, but the announcement may well weaken public confidence in the new system at the outset.

The position at Milford Haven, however, has implications elsewhere, and it is in the light of what has already been decided there that the proposal to place a nuclear power station at Trawsfynydd in the Snowdonia National Park should be considered. The Commission has already expressed its concern to the Minister of Power, and a public inquiry has opened since its annual report was issued. Lord Strang, in addressing the Council for the Preservation of Rural Wales, said explicitly that although there is a *prima facie* case for saying that the facilities offered by Milford Haven cannot be found in comparable degree elsewhere, it is not clear that any such argument can be advanced for the location of a nuclear energy station in the middle of the Snowdonia National Park. It does not appear, in fact, that any comprehensive survey of alternative sites has been even contemplated by the Central Electricity Authority, and although the Commission has already informed the Minister that this development appears to be incompatible with the maintenance of the area as a national park, it is already apparent that the local authorities, to which, in defiance of the National Parks Act, the Minister of Housing and Local Government has entrusted the administration of the Park, cannot be relied on to set the national before supposed local interest. The Merioneth County Council has from the start welcomed the scheme and set local employment before the national interest of amenity.

Evidence given at the inquiry on February 13 put a new and alarming face on a proposal which now looks even weaker than was supposed. Not merely is the life of the power station to be no more than twenty to forty years, but also, when the reactor reaches the limit of its effective life, it can be neither brought up to date nor demolished except at enormous expense, but must be left to cool down for perhaps half a century. The electricity plant, however, is still there and could be used or modernized, and also the network of power-lines. It would seem that the full implications of the nuclear power programme have not yet been considered.

What is to happen when the reactors are worn out? Will entirely fresh sites be sought, or will a fresh reactor be placed beside the first? It makes all the difference to the treatment of any proposal to enter an area such as a national park, if the encroachment is to be one of steady accretion. Indeed, if the life of a power station is to be only two decades or so, the argument against entering a national park area at all is almost unanswerable, while that for putting the reactor underground in any event is enormously strengthened.

What was disclosed at this inquiry has already made the very moderate and reasonable representations of the National Parks Commission quite inadequate. It is imperative, if preservation of amenity as a national interest has any meaning, that the full report of the inquiry should be published, and that the Ministers concerned, both the Minister of Power and the Minister of Housing and Local Government, should be pressed closely in Parliament to indicate clearly the views and intentions of the Central Electricity Authority in regard to the obsolescence and replacement of power stations, the implications of obsolescence and the policy they propose to adopt in regard to the protection of amenity. The cost of the whole programme for the development of nuclear energy needs to be reconsidered. If that programme is to threaten the national park areas, nature reserves and areas of exceptional natural beauty or scientific interest, it should include adequate financial provision for underground building or for the demolition of a reactor, at whatever cost, within, say, a decade of ceasing to use it. Until this is done, we are evading the real cost of nuclear power development and are betraying our trusteeship for our land and its natural beauty. The scale and pace of development have now taken us far beyond the point at which the nation can postpone paying the price demanded if anything of its natural and scenic heritage is to be preserved for this and future generations.

PASTEUR'S WORK ON FERMENTATION AND ITS SIGNIFICANCE FOR PRESENT-DAY STUDIES IN BIOCHEMISTRY

By Prof. T. K. WALKER
Manchester College of Science and Technology

IN 1858 Louis Pasteur turned his attention to the behaviour of yeast and made observations which were to have far-reaching consequences for the study of intermediary metabolism. Now, a hundred years later, it seems a suitable moment to attempt an assessment of the extent to which his work and his ideas are still influencing the direction of inquiries in biochemistry.

Although trained as a chemist, Pasteur laid great stress on physiological function in its relation to the chemical activity of yeast. Liebig, in 1839, had affirmed that the change of sugar to alcohol and carbon dioxide is effected by what he termed a 'ferment', a nitrogenous, unstable substance, formed in plant juices containing sugar when such liquids are exposed to air. The ferment was supposed to act by imparting its instability to the sugar. Pasteur believed alcoholic fermentation to be entirely bound up with the metabolism of the yeast cell, and his attitude in this matter was thus in striking contrast to that of contemporary workers of the Liebig school. After much controversy, Liebig's point of view became untenable when Pasteur demonstrated the ability of a strain of yeast to multiply and to set up alcoholic fermentation in a medium containing only pure sugar, ammonium tartrate and mineral salts.

Moritz Traube[1], in 1858, formulated a general theory of fermentation which he elaborated further in 1877. In his opinion, the ferments of putrefaction, fermentation and decay were substances of definite composition, allied to proteins and produced by living cells. He conceived the idea of 'reduction ferments', able to transfer the oxygen and hydrogen of water to different parts of the molecule of the fermentable substance, and so effect that apparent intramolecular oxidation and reduction first postulated by Lavoisier. Traube also pictured 'oxidation ferments' which could take up free oxygen and transfer it to oxidizable molecules, or groups of atoms, to bring about such changes as the conversion of alcohol to acetic acid or of ammonia to nitrate. He thus anticipated to a remarkable extent modern views on the enzymes effecting oxidation and reduction in vital processes.

Those reduction ferments which Traube envisaged as responsible for the evolution of free hydrogen in certain fermentations, were later to be identified with such reducing enzymes as those of the butyric acid-producing organisms, studied by Pasteur in 1861. Pasteur demonstrated their inability to grow in air and thus showed that the maintenance of life is not necessarily dependent upon the taking-up of oxygen from the external medium. These forms of life became known as 'obligate' anaerobes.

In 1872 Pasteur showed that highly aerobic organisms, such as *Penicillium glaucum*, which normally could oxidize sugar completely to carbon dioxide and water, gave rise to an alcoholic fermentation when deprived of air. Conversely, when yeast, an anaerobic organism, was grown in strongly aerated sugar media, he observed that reproduction of cells increased considerably while production of alcohol diminished. In other words, if oxidation is suppressed by lack of oxygen, fermentation is enhanced. This inter-relation became known as the 'Pasteur reaction' or the 'Pasteur effect'. Thus, Pasteur defined two kinds of life, the aerobic and the anaerobic. Later[2], in 1875, in reply to criticisms formulated by Traube, he was to make the categorical statement that: "Fermentation is the consequence of life without air, life without free oxygen. More generally, every living thing, every organ, every cell which has the power to perform chemical work without making use of free oxygen forthwith brings about phenomena of fermentation". Again[3], in the "Troisième réponse à M. Berthelot" (1879), and in other publications, Pasteur reiterated his doctrine that all fermentation phenomena are manifestations of the life of the causative organism.

What Pasteur now needed, in order fully to maintain his theory, were quantitative results to permit mathematical definition of the real relations between the presence of oxygen and the rate of fermentation, measured by weight of alcohol formed by unit weight of yeast in unit time. However, experimental techniques of that period were inadequate for this purpose and the matter was left unresolved until, some forty-five years later, Meyerhof was able to furnish the necessary figures.

In 1897, two years after the death of Pasteur, the brothers Hans and Eduard Buchner separated from yeast the cell-free preparation, zymase, which could set up alcoholic fermentation. As a consequence, the theory that fermentation was simply the manifestation of the action of an isolable enzyme held the field for some years and Pasteur's opinion received little consideration. However, after 1906, when Harden and Young had revealed the complex nature of zymase and the occurrence of phosphorylation of hexose in fermentation, the teaching of Gowland Hopkins and the work of colleagues inspired by him brought growing realization of the functional importance of the hitherto uninvestigated intracellular enzymes. As early as 1913, Hopkins[4] anticipated, with surprising accuracy, developments which were not to occur until some ten to twenty years later. In the words of Dr. Marjory Stephenson[5], he pictured the cell as: "the seat of ordered chemical events controlled in the interests of growth and function", and it is evident that in this picture the enzyme theory of fermentation is harmonized with Pasteur's[5] teaching. The details came slowly, however, for even a partial explanation of the Pasteur effect had to await the outcome of an immense amount of further original work by many gifted investigators. These researches cannot even be outlined here, but the principal findings may be stated, for now, at last, they permit understanding of some of the ways in which the Pasteur effect may be regulated.

The quantitative experimental data, which Pasteur had been unable to furnish in substantiation of his theory, came in 1925 from a series of experiments brilliantly devised and performed by Meyerhof[6]. Using the Warburg micro-respirometer, he found considerable differences in the extent to which fermentative functions of the cells of different types of yeast (wine yeast, brewers' bottom fermentation yeast, bakers' yeast and wild yeast) were diminished when aeration was increased. His results proved a striking confirmation of Pasteur's views; in particular, in the case of wild yeast (*Torula* sp.) the fermentative and oxidative powers of the cell were seen to be almost completely interchangeable; the respiratory power of these cells was so high that in presence of oxygen they were to the extent of 75 per cent an oxidizing mechanism. In anaerobic conditions they were pure fermenters.

Returning to Harden's discoveries, it could be said that these provided the basis for the highly important studies of glycolysis in animal tissues, undertaken in the first half of the present century by Embden, Meyerhof, Parnas, Warburg, Dr. and Mrs. Cori and D. M. Needham, all of whom contributed to our now extensive knowledge of the reactions proceeding anaerobically from glycogen to lactic acid in muscle. Simultaneously, further work on alcoholic fermentation by yeast and other organisms was undertaken by many distinguished workers, including Harden, Robison, Fernbach, Neuberg, Nord, Kluyver and Meyerhof. In the period 1910–13 it had been rendered probable by the work of Neubauer and of Fernbach that pyruvic acid takes a key role in fermentation. Neuberg confirmed this view and discovered in yeast the enzyme carboxylase; this decomposes pyruvic acid to carbon dioxide and the acetaldehyde which, on reduction, affords ethyl alcohol. By 1933 it had become clear that glycolysis in muscle and fermentation follow a common pathway from the stage of hexose-6-phosphate to that at which pyruvic acid is formed from glyceric acid phosphate. Muscle tissue, however, lacks carboxylase, so here the pyruvic acid does not suffer decarboxylation but is reduced to lactic acid. Experiments of Lohmann, and of Meyerhof with Lohmann and with Kiessling, showed that the intermediates are produced in phosphorylated form down to the stage of phospho-enol-pyruvic acid, and the quantitative data relating to yeast fermentation were found to fit exactly into the fermentation equation of Harden. Almost full knowledge of the enzyme systems which mediate in the twelve steps between hexose and pyruvic acid has been acquired since 1933. Most of these enzymic catalysts have been isolated and purified. All the stages from fructose-1,6-diphosphate to pyruvic acid have been found to be essentially reversible. The final stage of fermentation, namely, reduction of acetaldehyde to ethyl alcohol, catalysed by alcohol dehydrogenase, is also reversible.

Since the Pasteur effect expresses the inter-relations of the series of processes which take place during fermentation and respiration, it is now necessary to consider what evidence concerning the link or links between them has been afforded by the results of modern researches. The first suggestion that biological oxidations could be effected by coupled reactions with other enzyme systems had come in 1928 from Quastel and Wooldridge. In 1937 Szent-Györgyi[7] carried this idea a stage further by advancing the ingenious theory, backed by results derived chiefly from experiments with pigeon breast muscle, that the principal role of *l*-malate, fumarate and oxaloacetate in muscle is a catalytic one, that of carrying hydrogen between foodstuff and cytochrome. By combining Wieland's theory of hydrogen activation with Warburg's theory of activated oxygen and fitting Keilin's cytochrome into the system, Szent-Györgyi could now express the oxidation of a carbohydrate metabolite (the donator) as:

$$\underset{\text{(triose)}}{\text{Donator}} \xrightarrow{2H} \underset{\text{Activation by malic dehydrogenase}}{\text{oxaloacetate} \rightleftharpoons \text{malate}} \xrightarrow{2H}$$

$$\underset{\text{Activation by succinic dehydrogenase}}{\text{fumarate} \rightleftharpoons \text{succinate}} \xrightarrow{2H} WKS^{*}-O_2$$

* *WKS* = Warburg–Keilin system, by which hydrogen (or electrons) is donated to oxygen through the mediation of cytochrome and cytochrome oxidase.

This theory was not claimed as a complete explanation of carbohydrate oxidation in muscle, but it did constitute a notable advance in knowledge of the subject. Szent-Györgyi explained that the difference between glycolysis in muscle and oxidation lies in the fact that, anaerobically in muscle, hydrogen is transferred from triose to pyruvic acid, whereas in the presence of oxygen the hydrogen from triose is donated to oxaloacetate. Thus, to shift over from fermentation to oxidation requires nothing more than to carboxylate pyruvic acid and thus take the molecule out of the carbohydrate cycle and stabilize it as a catalyst. He suggested it was by carboxylation of pyruvic acid that Nature, in the course of phylogenetic development, changed to a process of oxidation the older and simpler process of fermentation. Szent-Györgyi[8] summed up in the statement: "According to this picture fermentation and oxidation thus represent alternate ways of metabolism. And this in part is probably the explanation of Pasteur's Effect".

While his conclusions were in course of publication there appeared the first of a most important series of papers by Krebs and colleagues in which the hypothesis of the tricarboxylic acid cycle was advanced and developed. Krebs[9] was able to show that the 4-carbon dicarboxylic acids in muscle are members of a more complicated cycle which starts from citric acid and ends in oxaloacetic acid.

After Werkman and Wood had detected the fixation of carbon dioxide by propionic acid bacteria, the synthesis of oxaloacetate from pyruvate and carbon dioxide was demonstrated by Krebs and Eggleston. This synthesis can occur in pigeon liver and in other cells from diverse sources. It is now believed that the citrate arises from union of oxaloacetate with acetyl co-enzyme A, the latter being derived from pyruvate. The Krebs cycle (tricarboxylic acid cycle) operates in living organisms of many kinds, and in animals it supplies much of the free-energy requirements of the cells.

Work by Warburg and by Keilin and Hartree twenty years ago showed that nearly the whole of the respiration of bakers' yeast is carried ultimately by cytochrome. Afterwards, claims were made that the earlier stages of respiration in yeast are those of the Krebs cycle, but there is also evidence for the view that the hexose monophosphate shunt pathway is followed.

The link between fermentation and respiration at the stage where pyruvate is carboxylated is only one of a number of inter-relations which give rise to the Pasteur effect. There is evidence that oxygen can suppress the action of several enzymes of the glycolytic pathway (for example, phosphohexokinase or triosephosphate oxidase) by oxidizing —SH groups essential for protection of these systems, and Barron[10] cites other examples of interfering influences.

Reviewing all these developments one may ask: Can this theme still inspire new pioneering inquiries? There can be no doubt about the answer when we perceive among contemporary studies Lipmann's work on energy-rich bonds and on co-enzyme A, Calvin's achievements in photosynthetic chemistry and the discoveries of Krebs and Kornberg on the role of glyoxylate in a modified tricarboxylic acid cycle, for all these researches arise from earlier work on fermentation mechanisms. Co-enzyme A comes into action, for example, in the processes by which carbohydrate is converted into fat, while the glyoxylate cycle can account for the conversion of fat to carbohydrate in, for example, *Ricinus* seedlings. Finally, it may be noted that the nucleotide co-enzymes of fermentation have lately engaged the attention of Sir Alexander Todd and co-workers, in their brilliant studies of nucleotides.

MECHANICS OF NORMAL MUSCULAR ACTIVITY

By Dr. R. J. WHITNEY

Medical Research Council Unit for Research on Climate and Working Efficiency, Department of Human Anatomy, Oxford

THE diverse aspects of the physiology of voluntary muscular activity have been recently reviewed[1]. A noticeable feature of current knowledge on muscle action is the often considerable gap that remains to be bridged between the comparatively simple properties of the artificially stimulated muscle preparation and the complex of activities which attends even the simplest muscular movement of the intact animal. Recently it has become possible to record, in greater detail than formerly, the forces and movements developed during the performance of normal, muscular tasks by the human subject. The special apparatus (force-analysis platform) used for obtaining this record has been described elsewhere[2]. In the interpretation of these records of normal muscular activity it has been found necessary to reconsider the subject of muscle mechanics, and to examine the possibility of applying the numerous results obtained with muscle preparations to an explanation of observations made on voluntary activity by the intact animal. This reconsideration has led to a conception of normal muscular activity which is, in many ways, different from that which is currently held or, at any rate, implied in modern text-books of physiology. This article is intended to indicate, as briefly as possible, the nature of this conception, the arguments on which it is based, and some of the uses to which it can be put to explain normal muscular activity. In general, what is said is concerned chiefly with the activity of skeletal 'power' musculature of the mammal.

It will be convenient to state, at the outset, the proposed hypothesis, and then to consider the arguments on which it has been based. The hypothesis states that the immediate result of the activation of a muscle via its normal nervous connexions is the production of an essentially oscillatory force. The frequency of the oscillation may vary in different muscles, but is of the order of 10 cycles per second in mammalian power muscles. The oscillatory response always has a component which does not vary, or which varies at a comparatively slow rate, in addition to the oscillatory component. The oscillatory component becomes more pronounced in stronger muscle actions. The apparent smoothness of muscle actions in the intact animal arises as a mechanical result of the application of the oscillatory force to masses—the masses being parts of the animal's body sustained against or moved in relation to external forces acting on the body parts. In the case of a man lifting or carrying a load, the mass of the load is added to that of the body parts also involved in the muscle action. The mechanical smoothing of the oscillatory driving force is never complete, so that normal muscular actions will always exhibit a small superimposed mechanical oscillation ('tremor') of the same frequency as that of the driving force. The value of this frequency is determined by an inherent property of contractile tissue (twitch-time). All the constituent fibres of a muscle are likely to participate in any sustained activity of the muscle, however slight this activity may be. Gradations of activity of the muscle are produced only partly by variations of the average rate of activation of the constituent muscle fibre. Variation of the degree of synchronization between the different muscle fibres is of comparable importance in the production of gradation of activity of the whole muscle.

It will be noted that the proposed hypothesis discards a number of views which have previously been expressed or implied with regard to the nature of muscular activity. In particular, tetanic responses of muscle are excluded as a normal feature. Tetanic responses of experimental muscle preparations have received considerable attention from muscle physiologists during the past fifty years or so, and it is still implied (for example, in text-books of physiology) that the nature of this response is of significance in the production of smooth action of muscle and in the gradation of muscular activity ('wave summation'). Lastly, the hypothesis rejects the view that muscle tremor arises as a property of sensory and neural mechanisms.

Tetanic activation of the individual muscle fibres of a muscle is precluded as a feature of normal muscular activity because direct observation of the discharge frequencies of the motor neurones which stimulate the fibres has shown that these frequencies would be inadequate to secure tetanic contraction. For tetanic contraction, artificial stimulation at frequencies greater than 50 impulses per second is required. Since Denny-Brown's[3] original observations, innumerable investigations have shown that the discharge frequency of the individual motor neurone rarely exceeds 30 impulses per second and is usually much less than this figure for normal, sub-maximal activity. For example, Bigland and Lippold[4], investigating the human gastrocnemius by electromyographic methods, observed maximum frequencies of between 25 and 35 per second during strong contractions of this muscle. These frequencies are much less than typical tetanic fusion frequencies of muscle preparations.

The basic response of the individual muscle fibre to stimulation via its normal nervous connexion is not, therefore, a tetanus but a twitch—that is, the response of the fibre to a single stimulating nervous impulse. The response is of an all-or-none character, and the force exerted (in an isometric twitch) or the shortening in length (in an isotonic twitch) follows a time-cycle which is completed, in the case of the constituent fibres of mammalian power muscles, in about 0·1 sec. (see, for example, Fulton[5]). The precise form of the force (or shortening)/time-curve during the activation-cycle of twitch has been discussed (see, for example, Sandow[6]). For purposes of computation the curve can be considered to approximate either to a harmonic or to a normal probability form. An appropriate harmonic form would be: Force (or shortening) $= A\,(1 - \cos 2\pi . t/T)$, where T is the duration of the activation cycle (about 0·1 sec.), t is any time during the activation cycle, and $2A$ is the peak force (or shortening). It will be obvious that no particular muscle fibre can complete more than $1/T$ (approximately 10) activation-cycles per second, and that for rates of activation less than 10 per second the particular fibre will exhibit discontinuous harmonic changes of force or shortening.

Completely synchronous activation of all the constituent fibres of a muscle (the number, in a human muscle, may exceed 1 million) is obviously not simply available in the intact animal. This generalization follows from two considerations: first, the conduction times between motor neurone and muscle fibre will vary; and secondly, complete synchronization of the motor neurone pool serving all the fibres of the muscle would be required. Since the motor neurone pool of a muscle may consist of several hundred motor neurones, spatially separated in the spinal cord, complete synchronization would be difficult to attain. For these reasons, the conception arises that the constituent fibres of a muscle must be activated, during voluntary contraction, in an essentially statistical manner. The muscle fibres are never, however, activated in a completely independent or random manner, because several hundred fibres (of a motor unit) are stimulated by a single motor neurone, and this will constitute a fixed synchronizing factor. Moreover, a variable physiological synchronizing factor probably exists, whereby the firing of the separate neurones of a motor neurone pool is progressively synchronized with increased afferent inflow to the spinal cord from the receptor organs of the muscle and from higher levels of the central nervous system (see, for example, Lloyd[7]).

The considerations raised in the preceding paragraphs suggest that the mechanical action exerted by a whole muscle at its origin and insertion on skeletal structures should be mathematically predictable by suitable summation of the mechanical actions exerted within the muscle by its constituent muscle fibres. Since the constituent mechanical action must vary with time, the total mechanical action must be predicted against time. The essential mathematical problem in the prediction is the summation of a large number of discontinuous harmonic changes, each of these changes being regarded as similar in all respects and the phase relations between the separate changes more or less randomly distributed. A formal mathematical treatment of this type of problem is not known to me, but a provisional solution has been attempted and has yielded the following results.

(*a*) The predicted total action of the muscle consists always of two components: a steady component which remains constant against time if the average rate of activation of the individual muscle fibre remains constant; and a continuous oscillatory component, the period of which is the activation cycle time (twitch time) of the individual muscle fibre. Thus, in mammalian power muscle, the oscillatory component will have a frequency of about 10 cycles per second.

(*b*) The magnitude of the steady component, for a muscle with a given number of constituent fibres, is directly proportional to the average rate of activation of the individual muscle fibre. The magnitude is not dependent on variation of the degree of synchronization between the fibres.

(*c*) The amplitude of the oscillatory component will be chiefly dependent on variation of the degree of synchronization between the fibres. The provisional solution suggests, for example, that the synchronization introduced by organization of a muscle into motor units of 100 muscle fibres per unit would give an amplitude 1,000 times greater than it would be if all the fibres were independent (asynchronous).

(*d*) To a lesser extent, the amplitude of the oscillatory component is also dependent on the average rate of activation of the individual muscle fibre. According to the provisional solution, the amplitude decreases with increase of rate of activation.

(*e*) It follows, from these mathematical results, that the peak force exerted by a muscle for a given average rate of muscle fibre activation would be progressively increased as the degree of synchronization between the fibres increased. The nature of gradation of muscle activity visualized by the hypothesis is summarized in Fig. 1.

The utility of these results in explaining certain aspects of normal muscular activity can be illustrated by reference to the following: (1) tremor during muscular activity; (2) muscular movement at uniform velocity; (3) the evaluation of 'static work' by muscle.

Since the original observations of Schäfer[8] there have been recurrent references to the tremor, of about 10 cycles per second, which appears to accompany muscular activity, particularly in mammals. This subject has recently been briefly reviewed[9]. Attempts have been made to account for this tremor as an oscillatory property of nerve–muscle servomechanisms. The hypothesis outlined above provides a much simpler explanation. Investigations of

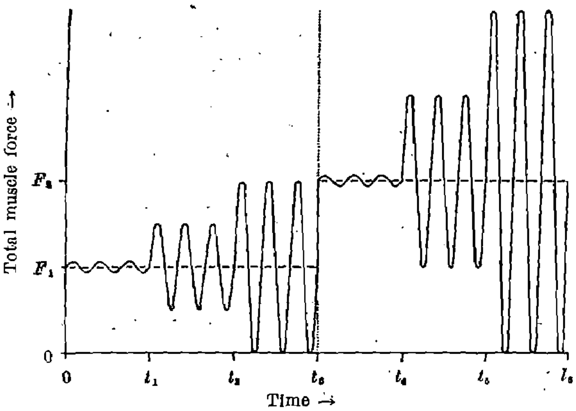

Fig. 1. Predicted effect of rate of muscle fibre activation, and of degree of synchronization between fibres, on the total muscle response due to statistical summation of responses of constituent fibres.

Two rates of muscle fibre activation, giving steady force components of F_1 and F_2, are represented. The effect on the oscillatory component and on the peak force is shown for three degrees of synchronization for each rate of activation. Time intervals t_2–t_3 and t_5–t_6 are for complete synchronization of fibres. The period of the oscillatory component remains constant throughout and equal to the twitch-time of the contractile tissue

postural tremor in man, using the force-analysis platform already referred to, indicate a progressive increase in amplitude of tremor with increased load on the musculature. This result is, of course, in agreement with the hypothesis.

The predominance of the oscillatory component in strong muscle actions, as predicted by the hypothesis, also provides a rational explanation of muscular movement at uniform velocity. It appears, from observations on man made with the force-analysis platform, that many muscular actions, such as postural readjustments and the lifting of weights, take place at almost uniform velocity. If muscle activation resulted in a steady force of the type observed in tetanized experimental preparations, accelerated movement of masses by the muscle would alone be possible. The dynamics of an oscillatory force applied to a mass shows, however, that all types of motion are possible, including uniform velocity. With the oscillatory force, a small tremor, of the same frequency as that of the applied force, is superimposed on the chief component of motion. The presence of such tremors, at frequencies of 10–12 cycles per second, has been confirmed for lifting actions carried out by man.

The oscillatory hypothesis of muscle action provides a very satisfactory conception of the nature of 'static work' by muscle. Static work is performed by a muscle when it maintains the position of a mass against an opposing external force. For example, postural muscles are required to perform static work against gravity if a certain posture is maintained and, in the case of a man holding a load against gravity, static work is performed by the muscles involved in the holding task. The evaluation of such static work in ordinary mechanical terms presents considerable difficulty if it is supposed that the task of maintaining position is performed by a steady force of the tetanic type (see, for example, Starr[10]). With a predominantly oscillatory muscle force no such difficulties arise. For example, if a mass M gm. is just sustained against gravity by an oscillatory muscle force of period T sec., then it follows from simple dynamics that the muscle performs ordinary physical work at the rate of $Mg^2T/2\pi^2$ ergs/sec. This treatment of static work may be employed to estimate the energy cost of standing upright in man, on the assumption that the whole body-mass is sustained against gravity by muscle action. If T is taken to be 0·1 sec., the estimated energy cost for a 70-kgm. man is 24 kgm.cal. per hour. This theoretical estimate is surprisingly similar to experimental values for the cost of standing obtained by indirect calorimetry, values of between 25 and 30 kgm.cal. per hour being observed by several authorities (for example, McCormick[11]).

These preliminary conceptions of the nature of normal muscular activity are being further developed, both theoretically and experimentally, and a fuller account of this work will be given elsewhere.

THE TIDAL MODEL AT THE UNIVERSITY OF SOUTHAMPTON

By Prof. P. B. MORICE

THE tidal model of Southampton Water and the Solent at the University of Southampton was built and initially operated under a research contract from Caltex Services, Ltd., which are considering the construction of a new oil refinery off Hook in Southampton Water, just south of the mouth of the Hamble River. The refinery would be supplied from tankers lying in a specially dredged widening of the channel.

The object of the model investigation was to forecast the new tidal velocities resulting from the changed conditions due to dredging, in order to ascertain whether the bed would remain stable. This is of particular importance to the Southampton Harbour Board, since the existing channel has been made largely self-maintaining with only a relatively small amount of repeated dredging.

The position of the proposed dredged region so close to the southern end of Southampton Water precluded a model of Southampton Water only, since the tidal streams at this point are never stationary throughout the whole tidal cycle, and the flow in and out is far from rectilinear. The model was therefore limited at the next convenient boundaries—Hurst in the west and Gilkicker in the east (Fig. 1). This introduced a unique feature into

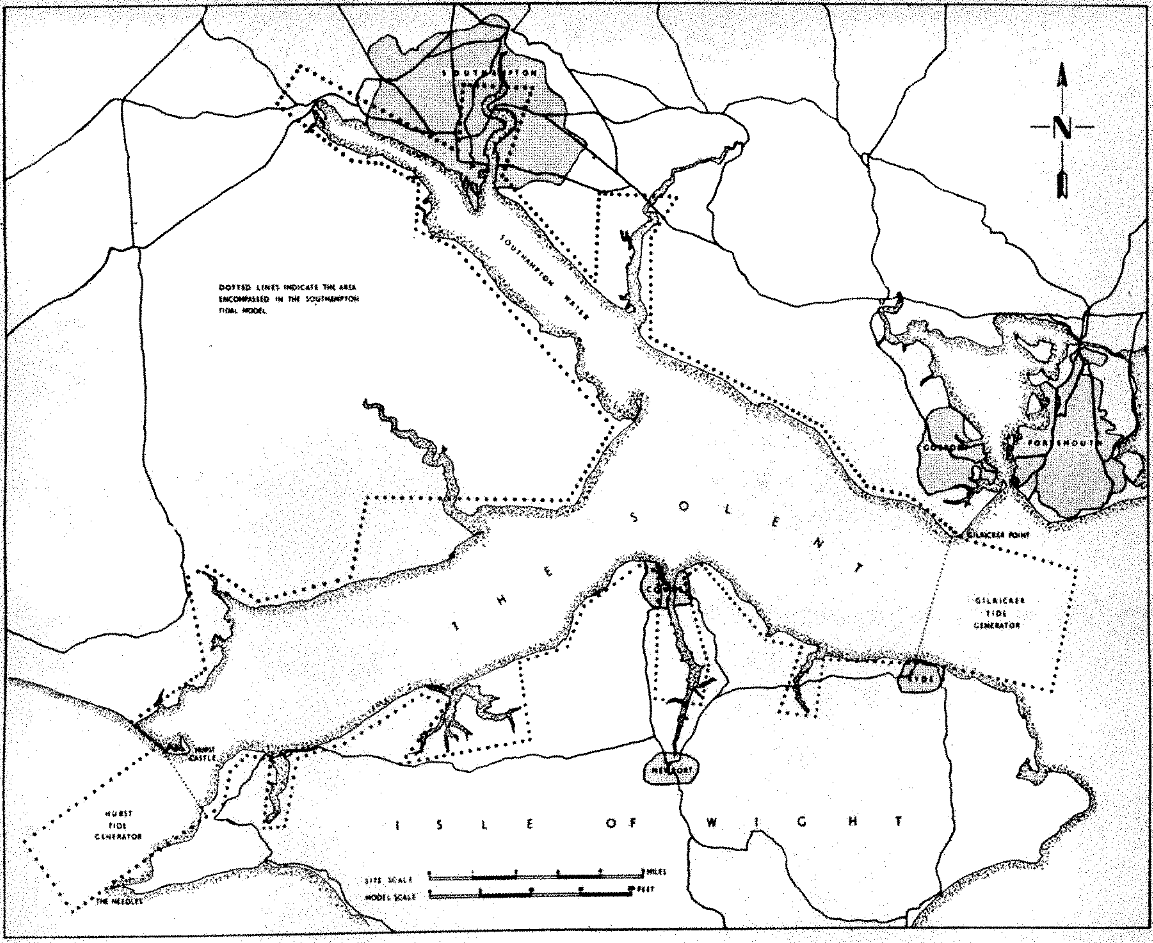

Fig. 1. Area covered by the tidal model of the University of Southampton; dotted lines indicate the boundaries of the model

the model (Fig. 2), since two tidal generators were required.

The horizontal scale of the model (1 : 1,250) was determined by the maximum dimension, that from Hurst to Gilkicker, some 20 miles in Nature, and the dimensions of the channel where the information was required. The vertical scale (1 : 100) enabled model tidal ranges of practical proportions to be used, while the exaggeration (12·5 : 1) did not cause excessive bed slopes. As a result of these choices, the velocity and times scales are fixed; namely, velocity-scale 1 : 10, time-scale 125 : 1. This latter gives a convenient tidal cycle period of 6 min. in the model

The tidal generators used in the model operate pneumatically, water being drawn into or released from tanks by changes in the tank air-pressure, which is controlled by valves allowing atmospheric leak into lines continuously extracted by high-speed pumps. The loads on these pumps are sufficiently steady to give good stability.

The tidal effects in the English Channel appear to result primarily from the excitation of a standing oscillation in the water mass extending from Land's End to Dover. The lowest frequency mode has a nodal line extending from Bournemouth to Cherbourg which, however, is distorted by the Earth's rotation to an effective nodal point inland of Bournemouth.

This system causes larger tidal ranges at the Gilkicker end of the Solent than at the Hurst end and greatly increases the range on the French coast. Superimposed upon the fundamental frequency at $12\frac{1}{2}$ hr. are many secondary effects (more than thirty components are required in a full harmonic analysis) the best known of which is the 'half-tide stand' or 'double high-water', known outside as well as inside the Solent. This gives Southampton its useful long slow flood and short fast ebb.

The main feature of the current system is a large flow back and forth in the Solent, with a relatively small quantity of water flowing in and out of Southampton Water and, so far as is known, no resultant circulation around the Isle of Wight, although this had been allowed for in the model by provision of an external connexion between the tidal generator tanks.

It is intended that the whole range from neap to spring tides should be produced by an electronic control system, but initial difficulties in the system made it necessary to obtain the information originally required by controlling the valves by motor-driven cams, prepared by a process of successive trial and error. For the present, the model operates on a maximum spring tide cycle only, which undoubtedly gives the maximum current velocities.

For the work in hand the model has been constructed with a hard bed. The bed was shaped by

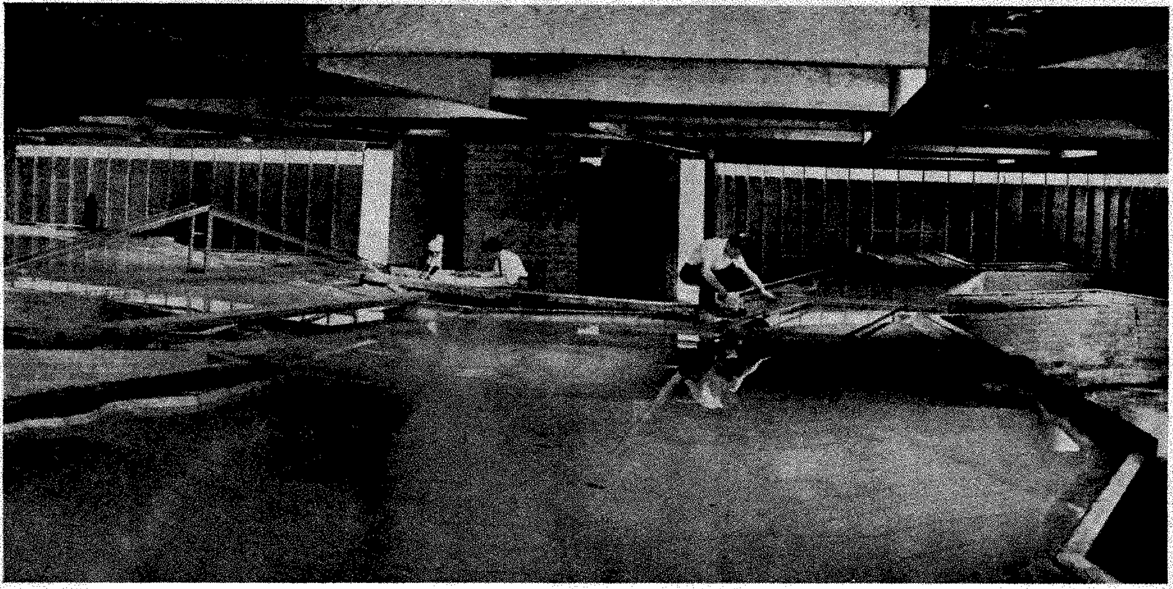

Fig. 2. View of the tidal model of the University of Southampton, looking north-west

hardboard templates made as profiles from charted information and spaced at approximately 1-ft. intervals on the model. A ½-in. mortar screed was placed between the templates and was given a brushed finish, which fortunately seems to have provided almost the correct degree of roughness to the surface. The rivers of the region are included to the extent of their tidal reaches; but it was concluded that none has a significant flow, so that this effect might conveniently be ignored, at least for the time being.

The recording equipment at present used in conjunction with the model includes capacitor-transducer level recorders and a movable integrating current-meter.

The model has already satisfied the Southampton Harbour Board that the proposed dredgings are likely to be stable; and a number of projects concerning changes to the regime have been proposed, for which the model will be used to predict full-scale effects.

The construction of the model was carried out under the direction of Dr. W. Wright (now professor of civil engineering, Trinity College, Dublin) with the assistance of Prof. A. N. Black and his colleagues and Commander D. H. Macmillan, of the Southampton Harbour Board.

NEWS and VIEWS

Pembroke College, Cambridge: Prof. W. V. D. Hodge, F.R.S.

Prof. W. V. D. Hodge, who has been pre-elected master of Pembroke College, Cambridge, will take up his duties there in August. Prof. Hodge, who has held the Lowndean chair of astronomy and geometry in the University of Cambridge since 1936, has achieved an international reputation as a geometer, mainly through his creation and development of the theory of harmonic integrals. The importance of his pioneer work in this field was recognized by the award to him, last year, of a Royal Medal by the Royal Society. He is also the joint author of the important three-volume work, "Methods of Algebraic Geometry", a careful exposition of modern algebraic investigations into the foundations of this subject. In addition to leading a vigorous school of research, he has taken an active part in University administration, having served on the Council of the Senate and on the General Board of the Faculties. Last November he succeeded Sir David Brunt as physical secretary of the Royal Society.

Engineering Structures at the Imperial College: Prof. S. R. Sparkes

Dr. Stanley Robert Sparkes, who has recently been appointed to the new chair of engineering structures in the Department of Civil Engineering in the Imperial College of Science and Technology, London, graduated in the University of Bristol in 1932; he was awarded an industrial bursary by the Royal Commissioners for the Exhibition of 1851 and gained practical experience in the design of steel structures with Messrs. Dorman, Long and Co., Ltd. In 1935 he joined the staff of the Department of Civil Engineering at the Imperial College and has been attached to it ever since. At the outbreak of the Second World War he was seconded to the Ministry of Supply for duty in connexion with air-raid precautions in building structures, and in 1942 he spent some months in India as structural precautions adviser to the Government of India. In 1944 he returned to the Imperial College, where he was appointed reader in civil engineering in 1947.

With the post-war expansion of the Imperial College and its consequent need for a considerable building programme, the then rector, the late Sir Roderic Hill, found it necessary to appoint a full-time planning officer and Dr. Sparkes was seconded from his Department to that post in 1953. In 1955 the importance of this work was recognized by making him director of building works. In that position, Dr. Sparkes has carried considerable responsibility for the new buildings already completed—the Roderic Hill Memorial Building to house the Departments of Aeronautics and Chemical Engineering, large extensions to the City and Guilds College and the Royal School of Mines, and additions to the Students' Union—as well as for much bigger work now under construction or on the drawing-board. Dr. Sparkes's research work has been in the experimental study of problems relating to building and ship structures and in the correlation of stresses as calculated in the design office with those found by measurement on actual buildings. With the large constructional programme now in progress in connexion with the expansion of the College, Prof. Sparkes will have unrivalled opportunities for continuing this work which is so necessary for a real knowledge of the behaviour of engineering structures.

Corday-Morgan Medal and Prize

THE Corday-Morgan Medal and Prize of the Chemical Society for 1956 have been awarded to Dr. K. W. Bagnall (Atomic Energy Research Establishment, Harwell) in consideration of his contributions to the knowledge of the chemistry of polonium. This award, consisting of a silver medal and a monetary prize of 200 guineas, is made annually to the chemist of either sex and of British nationality who, in the judgment of the Council of the Chemical Society, has published during the year in question the most meritorious contribution to experimental chemistry, and who has not, at the date of publication, attained the age of thirty-six years. Copies of the rules governing the award can be obtained from the General Secretary of the Society at Burlington House, London, W.1. Applications or recommendations in respect of the award for the year 1957 must be received not later than December 31, 1958, and applications for the award for 1958 are due before the end of 1959.

The Comptrollership of the Patent Office

QUESTIONED in the House of Commons on March 18 by Mr. F. T. Willey regarding the professional qualifications held by the newly appointed Comptroller-General of the Patent Office, the President of the Board of Trade, Sir David Eccles, said that the officer appointed has a first-class record as an administrator, and that he considered that to be the qualification most urgently required at the present time. When Mr. Willey asked Sir David if he realized that Britain is now the only major country in the world without a man of high professional reputation at the head of its Patent Office, thus reversing a policy thirty years old, Sir David replied that he considered the office required men of administrative ability at the top, but that he has requested the new comptroller to give scientists on the staff better administrative opportunities, with the view of reverting next time to the old method of selection. In a written reply to Mr. P. G. Williams on the same day regarding the reasons for the appointment, Sir David said that the functions of the Patent Office extend beyond the administration of the Patents Acts to questions relating to trade marks, designs and copyright, as well as to other matters such as international negotiations and agreements about industrial property. About two-thirds of the staff of 1,200 of the Patent Office, costing about £1 million a year, is non-professional, and the size of the Office and the complexity of management problems due to pressure of work and shortage of scientific staff have made the appointment of a comptroller-general of particular importance at this time. After weighing carefully the many considerations, Sir David said he decided that the primary need is for a comptroller-general with qualities of leadership and wide administrative and managerial experience. The appointment would be without prejudice to the selection of future comptrollers-general from within the Office.

The Patent Office appointment was discussed in an editorial article in *Nature* of March 15, p. 725.

Exchange Visits with the Soviet Union

MR. IAN HARVEY, Under-Secretary of State for Foreign Affairs, replying to a question in the House of Commons on January 27, said that there is a growing exchange of visits by students and teachers between Great Britain and the U.S.S.R., many of the visits being organized on the initiative and with the support of the Soviet Relations Committee of the British Council. In particular, the Committee, in partnership with British youth organizations, has invited 300 Russian students and young people to visit Britain for short periods. The Committee has also offered an annual exchange of twenty students of the Russian and English languages as well as two British Council scholarships for a full academic year and short courses for teachers, both on a reciprocal basis. Mr. Harvey also referred to the assistance given in these exchanges by universities and training colleges, and agreed that expansion of these facilities might contribute to mutual understanding between the two countries in a manner acceptable to both Governments. On March 17, Mr. Harvey said that the Committee still awaits a definite answer from the Soviet Union, although some progress has been made with the arrangements for the visit of 300 Soviet students and young people and two groups have already visited Britain. Any delay with the other proposals is entirely due to the Soviet side.

New Reactor at Harwell

HAZEL, a new zero-energy reactor, is now operating at the Atomic Energy Research Establishment at Harwell. HAZEL (homogeneous assembly—zero energy) uses enriched uranium fuel in the form of a salt of uranium (uranyl fluoride) which is dissolved in the heavy water used as a moderator. The core of the reactor is a stainless steel cylinder (7 ft. high × 2 ft. in diameter) surrounded by a graphite reflector. The fuel solution is pumped into the cylinder from two nearby storage vessels. The system is controlled by adjusting the level of the fuel solution in the reactor vessel and by moving a vertical neutron-absorbing cadmium plate into the gap between the steel cylinder and the graphite reflector. Two cadmium plates similar to the control device are used as 'shut-off' rods: two additional 'shut-off' rods can be dropped vertically into the fuel solution in the reactor vessel. The reactor will be operated at a power of less than a watt and cooling is not necessary. HAZEL will be used to obtain basic nuclear information. An earlier system at Harwell, ZETR (zero energy thermal reactor), was used to study solutions of nuclear fuel in ordinary water.

Atomic Energy

A NUMBER of questions on the peaceful uses of nuclear energy were asked by Mr. R. Mason in an adjournment debate in the House of Commons on March 20. Replying for the Government, Sir Ian Horobin, Parliamentary Secretary to the Minister of Power, said that from his inquiries at Harwell the question of the drift of leading scientists to the United States does not appear to be a very urgent problem at present. The storage and disposal of nuclear waste is a great trouble but not so far a major difficulty, and the present system of allowing the early decay to proceed and concentrate has not faced the Authority with any insuperable difficulties. The direct conversion to electricity from ZETA is a long way ahead and not at the moment a practical consideration. We now know a great deal more about the Wigner release, so that categorical assurance could be given that such an accident as that at Windscale could not recur. Moreover, the tendency is towards the use of higher temperatures and consequently, with graphite-moderated reactors, greater annealing of the moderator. The prospects of finding uranium in the United Kingdom are extremely slight. As regards secrecy restrictions, there is every evidence that Britain has been free from considerable difficulties which have arisen elsewhere, and he thought our approach has been sensible and moderate and also that we have found happier and more practical arrangements for partnership between the Authority and industry than some other countries. Considerable progress is being made in connexion with conventional stations, and it is thought that the economic difficulties of air-cooling might be sufficiently offset by savings in fuel transport when the stations are located nearer to coal. For nuclear power stations, the enormous usage of water renders the chance of economic advantage very slight. Sir Ian firmly defended the declassification and publication arrangements made in regard to ZETA and claimed that the matter had been handled well by the Authority, which was entitled to the confidence of the House and of the nation.

Human Sciences in Industry

ANOTHER stage in the development of psychology, sociology and related sciences in application to management, design and other industrial problems is marked by the decision of the Council for Scientific and Industrial Research to continue promoting research into the human problems of industry. In a written answer to a question in the House of Commons on January 21, Mr. H. Nicholls, the Parliamentary Secretary to the Ministry of Works, representing the Lord President of the Council, announced that the Council has set up a Committee on Human Sciences in Industry which will keep under review the development of the human sciences in relation to industrial needs, and will advise on the allocation of grants and on other means of promoting research in this field. On the side of the Department this Committee replaces the two former committees, on Human Relations in Industry and on Individual Efficiency in Industry, set up jointly with the Medical Research Council in 1953, agreement having been reached to replace them by separate committees reflecting the different interests of the two bodies.

A substantial flow of results is now coming from the research projects sponsored by those committees, on subjects ranging from psychological information theory applied to machine design to sociological aspects of technical change in the steel and other industries; the new Committee is expected to promote further applied research as well as more basic research in this field. Research and industrial interests are represented on the Committee, which has as chairman Mr. Lewis Wright (Amalgamated Weavers' Association), who is a member of the Council for Scientific and Industrial Research. The other members are Mr. P. W. S. Andrews (Nuffield College, Oxford); Mr. H. Briggs (Unilever, Ltd.); Prof. J. Drever (Edinburgh); Mr. E. Fletcher (Trades Union Congress); Prof. M. Gluckman (Manchester); Mr. H. G. Jones (Industrial Group, U.K. Atomic Energy Authority); Mr. H. G. Nelson (English Electric Company); Prof. E. A. G. Robinson (Cambridge); Miss B. N. Seear (London School of Economics); and Dr. A. T. M. Wilson (Tavistock Institute of Human Relations). The secretary is Mr. R. G. Stansfield.

Supply of Teachers in Schools and Technical Colleges

REPLYING for the Government in an adjournment debate on science teachers and National Service on March 17, Mr. R. Carr, Parliamentary Secretary to the Ministry of Labour and National Service, agreed most strongly with what Mr. W. Stones, Mr. E. Short and Dr. H. King had urged as to the importance of a sufficient number of adequately staffed technical colleges. Nevertheless he explained that, whereas technical colleges already have substantial help in their staffing problems from the existing arrangements for deferment, the even more favoured treatment of the secondary schools is a matter of deliberate policy, largely because of their greater need. In 1957 there were about 12,250 graduate teachers of mathematics and science in the schools and at least 300 unfilled vacancies. Between 1957 and 1964 the number of children more than fifteen years of age in the schools is expected to rise from about 250,000 to nearly 500,000, and even if the present net annual increase of 500 in science and mathematics teachers is maintained, sixth-form classes in those subjects are likely to be overcrowded. This is the first reason why the Government is concerned to do nothing that might interrupt the flow of such teachers into secondary schools. The second reason is that it is considered desirable that teachers in a technical college should have had some industrial experience, and that accordingly any concession to benefit technical colleges should also be given to jobs requiring similar qualifications in industry. This was recognized by the Willis Jackson Committee; the Government has moved a considerable way towards the more general and broader extension of deferment recommended by that Committee, but believes it is important to maintain a preference in favour of the schools. A third reason lies in the needs of the Services, which rely upon National Service to supply skilled scientific man-power until scientists can be recruited on a long-term basis. As regards the current position in the technical colleges, there was a net increase in full-time teachers of about 900 in 1956; for 1957 this was expected to be more than 1,000; and for 1958, about 1,400.

Technical Teacher Training

FOR the past ten years or so the technical teacher training colleges in Bolton, Huddersfield and London have had only some 350 places available in all. This number is now being increased by more than 60 per cent, and substantially higher grants are to be paid to students, in order to attract the right quality and quantity of candidates from those already settled in industry and commerce. Candidates are accepted as either 'private' or 'recognized' students for a course of one academic year. The latter pay no tuition fees, are offered free board and lodging in the college hostels and are eligible for maintenance allowances. To be accepted a candidate should normally have reached his twenty-fifth birthday, should possess a degree, Higher National Certificate or equivalent qualification and should have some commercial or industrial experience. Further information can be obtained from the Director, Huddersfield Training College, Queen Street South, Huddersfield.

Royal Society Expedition to Southern Chile

The Royal Society has announced that plans are being made, in co-operation with the Royal Society of New Zealand, to send a small expedition to southern Chile in September. Dr. Martin Holdgate, Zoology Department, University of Durham, has been appointed organizer, and Mr. G. A. Knox, Canterbury University College, New Zealand, and Dr. E. J. Godley, director of the Botany Division of the New Zealand Department of Scientific and Industrial Research, will also take part. The University of Chile has expressed its interest and also hopes to send representatives. It is intended that this expedition should be exploratory and preliminary to a proposed Commonwealth expedition to the South Pacific area.

Many genera and species of animals and plants occur both in South America and in New Zealand and Tasmania. The precise extent of this relationship remains uncertain, however, although its elucidation is clearly important for an understanding of biological evolution and of the past history of the Earth's surface. The fauna and flora of the world are now changing so rapidly through man's activity that it is likely that within another generation precise information about the natural distribution of animals and plants will be unobtainable, so that further research is needed urgently. A great deal of work has been done on the biology of New Zealand and its neighbouring islands, but by comparison southern Chile has been little studied. The present expedition's first visit will therefore be to the western hills of the island of Chiloe, where there are extensive tracts of dense evergreen rain-forest, and it will then proceed southward towards the Straits of Magellan. Ecological and geological studies will be made in the three areas it is proposed to visit, and peat samples will be collected from mountain bogs and lowland lakes in connexion with pollen analyses, from which it is hoped to learn something about past climatic and vegetational changes in the region.

Bardsey Observatory

The report of Bardsey Bird and Field Observatory for 1956 (Eglwysfach, near Machynlleth, Mont.: W. M. Condry, Hon. Secretary, 1957) contains details of many successful observations and developments. In a year of unusually heavy migration twice as many birds were ringed as in any previous season; more than a thousand birds were ringed at the lighthouse at night. Among the more unusual birds recorded were the melodious warbler, *Hippolais polyglotta*, and the greenish warbler, *Phylloscopus trochiloides*. During the year a visit was paid by botanists from the University College of North Wales, who surveyed the island's flora and prepared a species list, which is included in the report. The Observatory is open to visitors, particularly during the months of May, June and July. Further information can be obtained from W. M. Condry, Eglwysfach, Near Machynlleth, Montgomeryshire.

University News: London

The following appointments have been made: Dr. C. P. Whittingham, assistant director of research in botany in the University of Cambridge, to the University chair of botany tenable at Queen Mary College; and Dr. A. R. Flint, consulting civil engineer, to the University readership in structural steelwork tenable at the Imperial College of Science and Technology.

Announcements

Dr. G. A. H. Elton, at present reader in applied physical chemistry at Battersea College of Technology, has been appointed director of research of the British Baking Industries Research Association, Chorleywood. Dr. Elton's research has been mainly in the field of colloid chemistry. He was awarded the degrees of Ph.D. and D.Sc. of the University of London for work on this subject and for a number of papers which he has published in the field of rheology.

The Sixth Conference of the British Agricultural History Society will be held on April 10 and 11 at the Yorkshire (W.R.) Institute of Agriculture, Askham Bryan, York. Further information can be obtained from the Secretary of the Society at the Department of Agriculture, Parks Road, Oxford.

The Scottish Group of the Nutrition Society is holding a symposium on "Nutrition and Climatic Stress" at the Hannah Dairy Research Institute, Kirkhill, Ayr, on April 26, when papers will be read on both human and animal nutrition. Further particulars may be obtained from Dr. J. Davidson, The Rowett Research Institute, Bucksburn, Aberdeenshire.

The Scottish Branch of the Science Masters' Association is to hold its annual general meeting during April 10–12, in the University Chemistry Department, King's College, Aberdeen. The programme includes lectures, exhibitions and visits to places of scientific interest. Further information can be obtained from D. W. Menzies, Aberdeen Academy.

The Ergonomics Research Society is holding a conference on "Problems of Training" at the University of Bristol during April 13–16. Further information can be obtained from Dr. O. G. Edholm, Department of Human Physiology, M.R.C. Laboratories, Holly Hill, Hampstead, London, N.W.3.

The Operational Research Society is to hold an open conference at the Old Swan Hotel, Harrogate, during May 21–22. The conference will afford to representatives of commerce and industry an opportunity to discuss current applications of operational research. The main theme of the conference is "Aids to Decision Making". Further information can be obtained from the Honorary Secretary of the Operational Research Society, 3rd Floor, 20 Albert Embankment, London, S.E.11.

NATIONAL PARKS IN BRITAIN

THE eighth annual report of the National Parks Commission*, which includes confirmation of the Designation Order for the Brecon Beacons National Park, brought the number of National Parks established to ten, covering an area of 5,250 square miles. With the confirmation of the Commission's orders designating areas in the Gower Peninsula and in Lleyn and the Quantock Hills the first areas of outstanding natural beauty designated under Section 87 of the Act have been established, but the Minister's decision on the Surrey Hills area is awaited. Formal proposals for the designation of other areas on the Dorset coast and its hinterland, in Cornwall and Cannock Chase and on the Northumberland coast have been made to the local authorities concerned. The Commission also reports that though there has been no general relaxation of the restriction on capital expenditure, the Minister has enabled Park planning authorities to proceed with some tree planting and construction on car parks. Some quiet progress is reported in other matters also, such as the provision of cheap holiday accommodation for visitors with young families, anti-litter campaigns and caravan sites; but it is clear that, although in some areas progress has been made in the removal of misunderstandings and unreasonable criticism of the handling by the Park committees of applications for the supply of electricity, the Commission is still not entirely happy about the administrative arrangements resulting from the Minister's failure to insist on the provisions of the Act. There is also still room in all Park areas for the publicity activities which the Park Planning Board have been extending.

New rights of way were dedicated along some ten miles of the Pennine Way, leaving some 5½ miles outstanding, but progress in making footpath agreements for the approved Cornwall North and South Coast Paths remains slow. With the acquisition of some nine new miles along the Pembrokeshire Coast Path, 25 miles remain to be completed, and some 44 miles of new rights of way are still required for the Offa's Dyke route. Increasing attention is being given to publicity by the Commission itself, both for the Country Code and in attempts to make the National Parks more widely known and create public awareness of what is being done under the National Parks Act. Evidence was given to the Royal Commission on Common Land in which the National Parks Commission recommended that any body or person empowered to sanction change of use of commons, or to extinguish common rights, or to draw up schemes of management for commons, should, before any action were decided, receive representations from the local planning authority and, where National Parks or areas of outstanding natural beauty were concerned, from the National Parks Commission. The hope was expressed that common land would be given over to rotational cropping only where it was clearly in the national interest to do so, and that in forestry schemes landscape values would be protected so far as possible by the consultations already indicated. Management schemes designed to enhance the beauty of the landscape and preserve to the public the recreational use of the land were favoured, and the National Parks Commission stated that it would strongly oppose, save in cases of the most exceptional national importance, the use of common land for mineral extraction. An approach was again made, but without success, to the Chancellor of the Exchequer for provision in the Finance Bill, or in a separate Bill, for the reimbursement from the National Land Fund of expenditure on National Parks.

The outstanding feature of the Commission's report this year is once again that of development, and especially those represented by the proposals for a nuclear power station at Trawsfynydd. The Tryweryn Valley Water Scheme (in which the Liverpool Corporation withdrew entirely the Conway part of its scheme against which statutory and amenity bodies had petitioned) and developments at Milford Haven are going ahead, but the Commission affirms the view that large-scale industry should only be sited in National Parks in cases of over-riding and inescapable national necessity and in the absence of alternative sites elsewhere.

RECRUITMENT OF TEACHERS

SIR EDWARD BOYLE, Parliamentary Secretary to the Ministry of Education, replying for the Government in a debate on February 14, on the recruitment and training of teachers, said that he did not think that unemployment among teachers in the nineteen-sixties was to be feared. The cornerstone of the Government's educational policy was that the first priority should be a reduction in the size of classes, and although Sir Edward did not discuss other objectives such as compulsory part-time day release and raising the school-leaving age to sixteen still required for full implementation of the 1944 Act, he pointed out that decision on the timing of these objectives would be governed by, *inter alia*, the supply of teachers. The debate was a little too early for him to give the full picture, but over the seven years that ended in 1956 the increase in the number of teachers in maintained schools was about 6,500, but this now seemed to have dropped to just over 5,000. About 900 more training teachers should be going into the schools in 1958 than in 1957 and a further 700 in 1959. Recruits to teaching without professional training remained fairly steady at 700 a year, but there was a marked increase in graduates taking up first appointments in schools —from about 1,800 in the year ended March 31, 1956, to about 2,600 the following year. There had, however, been marked decline in the number of married women returning to teaching, from 2,300 in 1951–55, to just over 1,000 in 1956. Nearly 600 more teachers retired in 1957 than in 1956 and it seemed also that more women teachers resigned than in previous years. On this net annual increase of 5,000, if the present ratio of 21·5 pupils per full-time teacher was maintained in senior classes, the average size of junior classes could only fall to a little more than 31 by 1962. Major changes in policy, however, must await adequate information and consultation.

Sir Edward Boyle affirmed that the Government was absolutely committed to the three-year training course announced last summer, and much planning was proceeding to secure the best results from this advance. He entirely agreed that the training colleges must be up to date in curriculum and discipline, and he thought that conditions were improving. The standard of many libraries was excellent and the regime much more flexible. On the technical side, after referring to the Willis Jackson report, Sir Edward said that recent figures for recruitment of technical teachers were encouraging: an increase of 1,000 appeared probable in 1956–57 and for 1957–58 a total increase of 1,400 was anticipated. After stressing the need for close co-operation with industry, Sir Edward said that in principle the Willis Jackson Committee's recommendations regarding pre-service courses in the three technical training colleges had been accepted and that Dr. Willis Jackson had accepted the chairmanship of a new standing committee on the supply and training of technical teachers which had just been established.

After dealing in some detail with the assessment training grants for former members of the Regular Armed Services, Sir Edward referred to the question of specialist teachers, particularly of mathematics and science. Although the 12,250 graduate teachers of mathematics and science in the schools was an increase of 1,750 over the past five years, this was insufficient to maintain the staffing standard in these subjects. The demand for such teachers was expected to increase by 40 per cent between now and 1962, but the actual increase was estimated at only 27 per cent. In the long term, the best hope of avoiding overcrowded classes in mathematics and science in sixth forms during the coming years lay in a large increase in mathematics and science graduates from the universities and in an increased attractiveness of teaching as a career. Sir Edward hoped that industrialists would remember that it was in their own interest that science and mathematics should be well taught in the schools. The training colleges could help in some measure and had been asked to bear in mind the importance of mathematics and science in planning their courses and selecting students for training, and in the past five years the number of training college students taking main courses in mathematics had doubled; in science the number had risen by 75 per cent.

THE LEVERHULME TRUST

THE first report of the Leverhulme Trust on the Leverhulme Research Awards (pp. 72. London: The Leverhulme Trust, 1957) gives a record of the research awards, 1933–47, covering 273 made under the general scheme at a total cost of £130,299. Up to and including 1957, 612 were made at a total cost of £276,548, of which 580 costing £255,787 belong to the general scheme. The record is arranged in three sections: arts and humanities; natural sciences (including mathematics and medicine); and social science. In each section awards are listed chronologically by year and alphabetically for each year, giving the subject of research and relevant publications. There is an index of names and list of abbreviations for periodicals. The record is preceded by a historical note by Sir Hector Hetherington describing the circumstances which led to the establishment of the scheme, reviewing briefly its working and development and noting some of the problems encountered. The scheme was conceived mainly to help senior academic workers to complete their research projects, but it has never been restricted to the universities: many awards have been made to members of the staffs of national museums and galleries for study at home and abroad, and the primary purpose of the scheme continues to be to offer opportunities for periods of study and research which are not provided or inadequately provided by the official systems.

In general, the method used is to make good to the recipient any loss of income incurred by taking a period of study-leave and to meet such special expenses of the programme as could not be covered by other resources. Normally, the award, which has from the beginning been of no fixed amount, consists of two parts: a personal grant to replace earnings foregone, and a grant towards the special expenses of the programme.

The primary test of eligibility for a personal grant is that some loss of earnings should be incurred in undertaking the programme, and in general the Trust requires that the awards should be made for a significant period of time—at least three months, with an upper limit of two years. It is not at all concerned to pay the expenses of delegates to conferences or to other national or international gatherings. Recently the Trustees, however, have approved four further smaller schemes. In 1953 two 'European' awards were offered to young postgraduate scholars to meet the cost of a year of study in one or more centres of learning in Continental Europe. Two further schemes were developed for two or three years postgraduate study in a British university for candidates nominated by universities and university colleges in Africa and the West Indies. Four awards a year are also offered to graduates of British universities who wish to work for one or two years in the West Indies or in Africa, while finally three awards are offered each year to enable young graduates of certain major art schools to have a year of continuous study abroad, one of these awards being in the field of industrial design.

These recent policies are still regarded as experimental, and while awards have been made in almost every field of study, the Advisory Committee's working rule that no one project could be supported to the extent of more than 15 per cent of the resources available in any year has excluded a few very expensive schemes. The main area of concentration has been in age-group 40–60, but the spread extends from 27 to 80, and Sir Hector refers to the notable advantage of the private trust that it may more readily employ some of its resources as venture-capital to support a promising but more than ordinarily hazardous programme. It is intended to issue further reports at five-yearly intervals.

THE EUROPEAN NUCLEAR ENERGY AGENCY

THE European Nuclear Energy Agency was established to further the development of the production and uses of nuclear energy for peaceful purposes through co-operation among the participating countries, which include the United Kingdom and all the member countries of the Organization for European Economic Co-operation. It came into being on February 1, and the text of the Statute and related instruments was published as a White Paper on February 4*. The Agency will operate through a Steering Committee for Nuclear Energy and such other commissions and working parties as may be required, and the Governments of Canada and the United States are invited to associate themselves with the work of the Agency. Where appropriate, the Agency will promote the formation of joint undertakings for the production and application of nuclear energy for peaceful purposes, endeavouring to secure the participation of as many countries as possible, and it will do all in its power to ensure that joint undertakings as well as participating countries are regularly supplied with the necessary raw materials.

The Agency is instructed to examine jointly with the Steering Board for Trade measures to achieve the maximum freedom of international trade in products of interest for the production and application of nuclear energy and will encourage the development of research, promoting, where appropriate, agreements for the joint use of research installations, and the creation of joint research establishments, and also the exchange of scientific and technical information between participating and associated countries. It is also to promote the development of training in matters relating to nuclear energy so as to assist in meeting the demand for scientific and technical personnel in this field, both by encouraging co-operation to secure the full use and development of existing training facilities in competent national institutions and by encouraging legislation to secure the protection of public health and prevention of accidents in nuclear industry, the most efficient use of patented inventions and to provide for third-party liability and insurance against nuclear risks. The Agency is required to establish a security control to ensure that the operation of joint undertakings and the materials, services and equipment provided by the Agency or under its supervision do not further any military purpose, and the organization of this control is detailed in a special Convention, the text of which is included in the White Paper. The Convention provides for a central bureau assisted by a director and administrator and technical officers, in particular a group of international inspectors, as well as for a tribunal of seven independent judges appointed for five years.

The Statute also provides for close collaboration with the European Atomic Energy Community (Euratom), with which an agreement is to be made defining the arrangements under which the control established by the new Convention is to be carried out in Euratom territory. Agreement may also be made with the International Atomic Energy Agency for the same purpose.

STANDARD FREQUENCY TRANSMISSIONS FROM THE UNITED KINGDOM

A LIMITED programme of transmissions of standard radio frequencies was started in 1950 from the Post Office station at Rugby under the call sign *MSF*. This was extended in 1953 to the provision of a continuous service on the three frequencies of 2·5, 5 and 10 Mc./s. with periods of modulation by a 1,000 c./s. tone and by 1 c./s. pulses (see *Nature*, 172, 529; 1953). From the start these transmissions have been monitored at the National Physical Laboratory, which has just published a new edition of a pamphlet entitled "*MSF*—Standard Frequency Transmissions from the United Kingdom". This gives full technical details of the current programme, including reference to the additional transmission which is made for one hour each day on a frequency of 60 kc./s., and which provides a ground-ray service over a wide area inside the skip-distance of reception on the higher frequencies. This transmission has proved so valuable that the carrier wave of the 16 kc./s. *GBR* telegraph transmitter is now also controlled from the *MSF* standard although it is not yet regarded as part of the regular service.

The new pamphlet (obtainable free on application to the Director, National Physical Laboratory, Teddington, Middlesex) also announces that the *MSF* frequencies are now based on the resonant frequency of the caesium atom. Provisionally, the value of 9, 192, 631, 830 cycles per second has been adopted for this. This frequency is a fundamental physical constant, free from the small corrections and uncertainties associated with astronomical time. The precise value of the frequency is based on the value of astronomical time for 1955. Some years must pass before the astronomical and atomic units can be compared to the full accuracy attained by the atomic clock because astronomical time must be averaged over a long period to eliminate small errors and uncertainties of measurement. If any corrections prove necessary in years to come, they can readily be made and, therefore, will not restrict the accuracy already available.

The *MSF* frequencies and modulations are maintained to ± 5 parts in 10^9 but are monitored to ± 1 part in 10^{10}. Continuous measurements on the transmissions are made at the National Physical Laboratory, 120 km. distant from Rugby. The results, which are published monthly in *Electronic and Radio Engineer*, are given only to ± 1 part in 10^9 to allow for slight transmission and propagation errors, but even more precise average values can be used when steps are taken to eliminate these errors.

WATER RESOURCES OF BRITAIN

A BROADSHEET, "Policy for Water" (No. 418; January 27, 1958), issued by Political and Economic Planning, attempts to give the background to the problem of water resources and supply by sketching the history and development of the water industry and other organizations concerned with the exploitation, disposal and conservation of water. Current economic and technical problems of supply and demand and pricing are then reviewed, including the need for more information, and the Broadsheet next discusses the two main administrative problems: first, the urgent need for a comprehensive rationalization of local water undertakings; and secondly, the need for greater co-ordination in all matters concerning water supply, fisheries, drainage, etc.

Pending the publication of the reports of the sub-committees appointed by the Central Advisory Water Committee, Political and Economic Planning concludes provisionally that the water resources of Britain are likely to be adequate to meet foreseeable demands, but that much new capital must be expended if water is always to be available in adequate quantity or appropriate quality wherever it is needed. The Broadsheet points out that while water of high quality is essential for drinking purposes, low-grade water will often serve industrial needs, and it is desirable that increasing attention should be given to this aspect and that we should not continue to draw on our relatively scarce resources of pure water for purposes for which water of inferior quality would do equally well.

There are far too many authorities. A radical rationalization of the water-supply industries is long overdue and is essential for substantial progress, although the basic technical economic problems of water supply can only be served if adequate capital is provided. Procedures laid down in the current Water Acts are long and intricate, and further measures may be required to overcome the natural unwillingness of many authorities to acquiesce in their own extinction within a reasonable time.

DIATOMS FROM EQUATORIAL INDIAN OCEAN CORES

THE appearance of the ninth volume of the reports of the Swedish Deep-Sea Expedition 1947–1948* completes Dr. R. W. Kolbe's trilogy on the diatoms from the equatorial zones of the most traversed oceans. The material here reported consisted of twenty-three cores selected from those obtained from the Indian ocean by M/S *Albatross* under the leadership of Prof. Hans Pettersson.

The cores were taken with a Kullenberg sampler and some of them from a depth exceeding 5,000 m. were more than 11 m. in length. As the complete examination of so large a mass of material would be impracticable, three samples were usually taken from each, namely, one from the deepest layer, one from the uppermost layer, and one midway between. The cores chosen for this study had been shown by preliminary survey to contain diatoms, and after submitting the material to the usual acid-cleaning technique it was mounted for microscopical examination.

The cores selected were obtained from seven geographical regions: (1) Java, (2) East Indian Ocean, (3) Ceylon, (4) Maldives, (5) West Indian Ocean, (6) Seychelles, (7) African coast.

In this way samples were examined from inshore positions (68 m. depth) to positions of great oceanic depth of more than 5,000 m.

By his use of the term 'diatom assemblage' Kolbe has rendered a great service in stressing the relation, or lack of it, between the silica unicells of the sediments and the diatom flora living in the column of water immediately above them. This abyssal assemblage differs from the planktonic and benthonic populations from which it is derived not only in a reduced number of species, but by their differing numerical frequencies. This assemblage is therefore not a natural facies of living organisms but belongs to a thanatocœnosis. Further, the physico-chemical selection which is brought to bear upon dead and dying diatoms during their slow journey through great oceanic depths to the sea floor is largely responsible for the marked uniformity observed in the diatoms over wide regions of the ocean floor. Dr. Kolbe's researches have also led him to observe a marked similarity between the diatom assemblages of the Atlantic[1], Pacific[2] and Indian oceans, and that the most frequent species are not confined to any one area, and that they differ only by their relative frequencies in the different areas. For example, *Coscinodiscus nodulifer*, *Ethmodiscus* (fragments) and *Nitzschia marina* are the commonest and most frequent species in all three equatorial oceans. Five others, *Hemidiscus cuneiformis*, *Thalassionema* sp., *Coscinodiscus excentricus*, *Coscinodiscus lineatus* and *Coscinodiscus africanus*, are common to the sediments of the three areas, but differ in their relative frequencies in the different oceans. These eight species constitute what Kolbe describes as the dominant abyssal assemblage.

One of the most interesting problems in diatom occurrence in oceanic cores is that concerning *Ethmodiscus rex* (Wall.) Hendey. This diatom, the largest known, lives or has lived in the three equatorial oceans and enormous deposits of it have been recorded from various parts. It is one of the most common diatoms in the equatorial sediments of the three oceans. For example, an area of oceanic ooze some three thousand miles long by twenty wide, consisting almost entirely of *Ethmodiscus*, has been reported between Guam and Luzon. Kolbe also has found evidence of considerable deposits of this species in the Indian and Atlantic Oceans—yet records of living specimens in the plankton have been rare.

Kolbe seeks to explain the discrepancy between the scarcity of *Ethmodiscus rex* in the plankton and its abundance and frequency in oceanic sediments, by combining three possible hypotheses: (1) dysphotic habit, explaining the rarity of the species in plankton samples taken by usual techniques (Karsten's hypothesis); (2) periodicity of short duration of mass reproduction (Hendey's hypothesis); (3) resistance to corrosion (Kolbe's hypothesis). Kolbe is of the opinion that the great accumulation of *Ethmodiscus* fragments in certain limited areas of the sea floor may be explained by the complicated relations between currents, sea-floor topography, size and form of sediment particles, all of which might result in a constant deposition of particles of certain properties in certain circumscribed areas.

---

* Göteborgs Kungl. Vetenskaps- och Vitterhets-Samhälle. Reports of the Swedish Deep-Sea Expedition 1947–1948. Vol. 9: Sediment Cores from the Indian Ocean. No. 1: Diatoms from Equatorial Indian Ocean. By R. W. Kolbe. Pp. 50+4 plates. (Göteborg: Elanders Boktryckeri Aktiebolag, 1957.) 15 Sw. kr.

Thus *Ethmodiscus* fragments within a certain size range might be constantly deposited at a given place, and so form *Ethmodiscus* beds, while other particles less dependent on slow currents might be distributed in a very different way.

Those who have tried to understand something of the relation between oceanic deposits, and the distribution of the living plankton populations that contribute to their formation, will find Dr. Kolbe's stressing of the differences between thanatocœnesis and biocœnesis of the greatest interest.

It seems that these differences must be influenced by the following factors (among others):

(1) Chemical erosion, as stressed here by Dr. Kolbe.

(2) Rate of fall. Here the wide range in sinking rate of fragments derived from the one species *Ethmodiscus rex*, determined experimentally by Dr. Kullenberg, seems especially significant.

(3) Speed and direction of sub-surface currents. Recent physical observations, albeit in a very different part of the world, show that their speed may be much greater than Dr. Kolbe felt entitled to assume (cf. ref. 3).

(4) Extreme periodicity in local swarming of certain species of plankton diatoms, as postulated by Hendey[4]. Probably most plankton workers of long experience can recall odd instances supporting this view, but not, unfortunately, with regard to *Ethmodiscus* itself. The relative lack of samples from its apparent habitat is probably quite sufficient to account for this.

These four factors are very well presented in Dr. Kolbe's paper, but it is felt that yet another may be important:

(5) What might be termed the biological part in the breakdown and decay of plankton diatom frustules. The ingestion of frustules or fragments by mesoplankton animals may be repeated several times before they reach bottom, with the further probability of considerable bacterial action both before and after ingestion (cf. ref. 5). This may well be of great importance in determining which members of the biocœnosis remain recognizable in the thanatocœnosis.

One minor correction to Dr. Kolbe's paper is necessary. The record of dense swarms of *Ethmodiscus* in the Bay of Bengal does not occur in Collingwood's paper of 1868, in *Transactions of the Royal Microscopical Society*, the reference quoted, but in the discussion following the reading of the paper (*Quart. J. Micr. Sci.*, 115; 1868), as Hendey has explained. The paper has now become a rarity, and some of the surviving separates do not include the discussion. The actual observations concerning *Ethmodiscus* in the Bay of Bengal seem to have been made by Dr. Wallich in 1851 and 1857.

The number of benthonic diatoms (112 taxa) observed in the material was 56 per cent of the total and was far greater than in the sediments of the Atlantic and Pacific Oceans. This is accounted for by the number of cores taken close to land. The high number of benthonic forms taken from the vicinity of the Seychelles archipelago, however, presents several interesting problems, as the cores were taken at great depth and far from the African mainland. It is suggested that their presence indicates that the whole district may have formerly belonged to a shallow sea and that its floor might have sunk to its present considerable depth at a not very remote period. The benthonic diatoms are, with very few exceptions, provided from thirteen of the twenty-three cores examined. The cores from the Ceylon, Maldives, and East Indies areas provided but six species. The paucity of *Triceratium* species, particularly those belonging to the *T. favus* group, and of *Mastogloia* and *Amphora* in the Java cores is surprising, as these genera are well represented in the area. The occurrence of species of *Stictodiscus*, usually considered to be extinct, at widely separated areas is significant. Mann[6] showed in his work on the diatoms of the Philippine Islands that the genus is well represented there and it may be that isolated pockets of these species have persisted since the Tertiary. Those in the African cores were found at depths varying from 4 cm. to 10 m.

Dr. Kolbe is to be congratulated upon completing this very considerable task without yielding to the temptation of making a host of new species out of the wide range of variants that the abyssal assemblage offered.

SOLAR ACTIVITY AND RADIO COMMUNICATION

By R. NAISMITH

Radio Research Station (Department of Scientific and Industrial Research), Slough

SEVERAL years ago the period 1957–58 was selected as the International Geophysical Year in the expectation that it would coincide with a period of high solar activity. This long-term prediction has proved quite successful, since it is actually coinciding with the highest period of solar activity which has occurred within the past two hundred years. The success of this long-term prediction, however, must be considered in relation to a comparatively large number of failures which make anyone who is aware of the difficulties involved reluctant to make long-period predictions until more is known of the causes of the variations.

There are, however, particular parts of the sunspot cycle which can be more accurately predicted than others for intermediate periods up to twelve months.

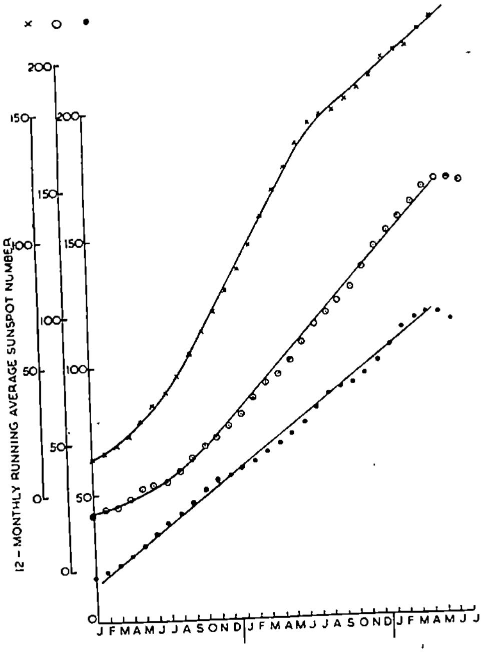

Fig. 1. ●, 1935–37 ; ⊙ , 1945–47 ; ×, 1955–57

These predictions are very useful in relation to radio communication, etc. This occurs, for example, during the rising period of each cycle, particularly when the maximum tends to be high. The last three cycles, which are good examples of this, are shown in Fig. 1. The prediction is associated with the linear rise, which may persist for periods of eighteen months or more. The end of this part of the current cycle is near, but there are features which may be associated with the present and future period of the current cycle to which attention should be directed.

In Fig. 2 the data plotted in Fig. 1 have been extended to cover a period of about two and a half years after the maximum of the cycle, and it will be noted that there is a general correspondence which may be used by a forecaster to estimate values for some time ahead. This is by no means a universal happening; but if the higher level of the present cycle should be maintained, the sunspot numbers during the next six months will be higher than those at present forecast by any organization making regular forecasts.

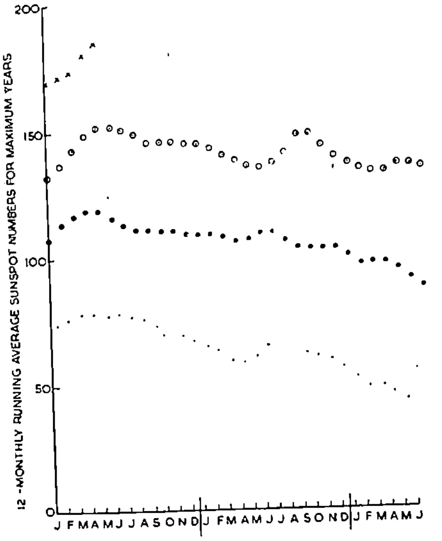

Fig. 2. ●, 1928–30 ; ●, 1937–39 ; ⊙, 1947–49 ; ×, 1957–

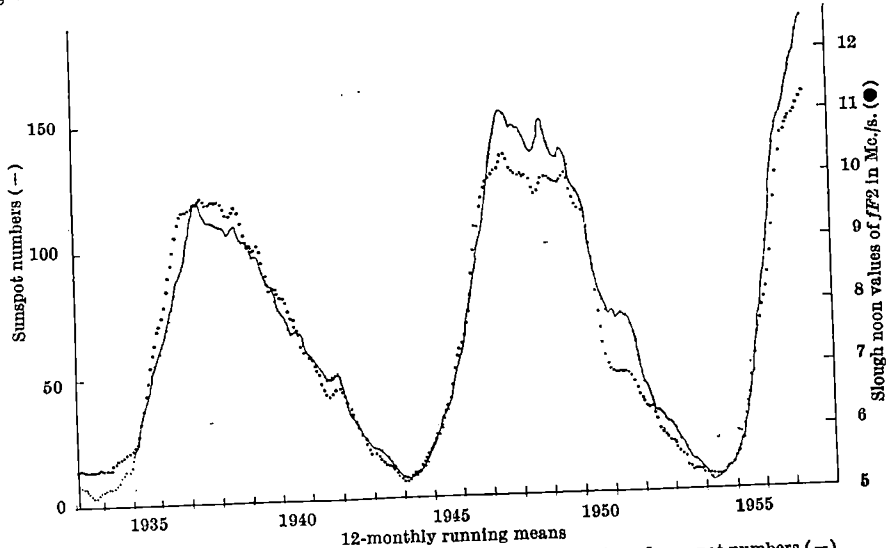

Fig. 3. Comparison of noon critical frequencies of *F*-region (●), and sunspot numbers (—)

In consequence of this, it is probable that higher radio-frequencies may be used for communication during the first half of 1958 than those forecast. The association of radio-communication conditions by way of the *F*-region of the ionosphere, as denoted by the variations in the noon critical frequencies (*fF*2) of that region as measured at Slough, and the solar activity as denoted by sunspot numbers, is shown in Fig. 3. This covers two and a half sunspot cycles, and this is the whole period for which the ionospheric measurements are available. Although neither the solar nor ionospheric index is perfect, they are both convenient for this purpose of comparison, and the agreement, even in some detail, reflects the close association of these two quantities when average values are considered.

This leads naturally to some useful data for radio-communication purposes. It is important, for example, to be able to distinguish between those radio-frequencies which may be used for long-distance radio communication by way of the *F*-region and those frequencies which, apart from a residual amount of scattering, will penetrate the ionosphere and will not reach great distances. For this purpose, use can be made of the sunspot data extending back over the years indicated in the first paragraph.

When interpreting the radio data, account must be taken of a well-known seasonal variation in the noon values of *fF*2 as recorded at Slough. This shows a very definite maximum during the winter months. It happens that the sunspot number for December 1957 was 244 and therefore greater than the twelve-monthly average for the maximum period of the present cycle. The monthly median value of *fF*2 at noon at Slough in December was 15·2 Mc./s., the highest December average value recorded at Slough since measurements were begun twenty-six years ago. This leads to the conclusion that the maximum frequency available for the longest-distance radio communication at the latitude of Slough would be close to 50 Mc./s. at noon for half the days in the month. This 'demarcation' frequency has some useful practical applications in planning radio communication in temperate latitudes.

The work described above was carried out as part of the programme of the Radio Research Board, and this communication is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

CHLORAMPHENICOL-RESISTANT INCORPORATION OF AMINO-ACIDS INTO *STAPHYLOCOCCI* AND CELL-WALL SYNTHESIS

By Dr. J. MANDELSTAM and Dr. H. J. ROGERS
National Institute for Medical Research, London, N.W.7

THE incorporation of radioactive amino-acids into the protein of bacteria, whole tissue cells and various sub-cellular fractions has been widely used as a method of studying the biosynthesis of proteins. In this context, 'protein' is usually defined, in practice, as the residue remaining after extraction with hot trichloroacetic acid and organic solvents. The appearance of radioactive amino-acids in this residue has often been accepted as a measure of protein synthesis. However, Gale and Folkes[1] examined the situation in which a single radioactive amino-acid was supplied to *Staphylococcus aureus* and found that, although there was no net increase in protein, the label was incorporated steadily for at least 2 hr. Furthermore, the incorporation of single amino-acids was much more resistant to chloramphenicol than protein synthesis. The authors therefore concluded that incorporation of a labelled amino-acid was not necessarily an indication of protein synthesis and suggested the possibility of an exchange reaction between the labelled molecules and the corresponding residues within the protein.

This type of reaction does not appear to be general, for other work has shown that, in *Escherichia coli*, the incorporation of glycine and leucine is almost totally suppressed by growth-inhibitory concentrations of chloramphenicol[2], and the same is true for incorporation of methionine and leucine in *Bacillus cereus* (Urbá, personal communication).

It is noteworthy that amino-acid incorporation in *Staphylococci* is particularly resistant to chloramphenicol in the case of those amino-acids now known to be associated with the cell wall. It therefore seemed possible to us that, when the organisms are incubated with a single amino-acid such as glycine or glutamate, the incorporation observed might be the result of synthesis of cell wall which, in *Staphylococci*, contains five amino-acids (glycine, alanine, glutamic acid, lysine and serine) and two amino-sugars[3]. Accordingly, experiments of the following type were carried out.

Staphylococcus aureus, Strain 524 55/*SC*[4] was grown in a casein hydrolysate medium supplemented with thiamine, nicotinic acid and 0·5 per cent glucose[5]. When the culture had reached a density of 1 mgm. dry weight of cells/ml., the bacteria were harvested and washed twice with 0·05 *M* phosphate buffer, *p*H 7·0, and suspended at a density of about 1 mgm. dry weight of cells/ml. in the same buffer solution containing 0·5 per cent glucose, 400 μgm./ml. of labelled amino-acid and 70 μgm./ml. of chloramphenicol. The suspension (150 ml.) was shaken at 35° C. for 60 min. in a one-litre conical flask. A portion of the cells (obtained from 15 ml. of the suspension) was treated with hot trichloroacetic acid and organic solvents and then dried[2]. This will be referred to as 'protein' and contains both the cell wall and the true cell proteins. The rest of the bacteria were washed, suspended in water at a density of 10 mgm./ml. and disrupted by shaking with glass beads for 15 min. Cell wall was separated, washed with water, treated with ribonuclease and trypsin followed by digestion with pepsin[3]. The cell-wall material was then washed several times with water and then with acetone and ether and finally dried. The supernatant from the disrupted cells after removal of cell wall, together with the water washings, was treated with an equal volume of 10 per cent trichloroacetic acid and left at 2° for 30 min. The precipitate was extracted with hot trichloroacetic acid and organic solvents and dried. This will be referred to as the 'true protein' fraction. Radioactivity of samples was measured at infinite thickness in a thin end-window Geiger–Müller counter. In some of the experiments involving glycine, samples of cell wall and 'true protein' were hydrolysed, the glycine isolated by paper chromatography and its specific activity determined[2]. In addition, samples of 'protein' and cell wall were hydrolysed for 4 hr. with 4 *N* hydrochloric acid at

Table 1. DISTRIBUTION OF RADIOACTIVITY INCORPORATED INTO PROTEIN AND CELL WALL BY *Staphylococci* IN THE PRESENCE OF GROWTH-INHIBITORY CONCENTRATIONS OF CHLORAMPHENICOL

	Specific activity of cell fraction (counts/min.)			Increase in cell wall (per cent)
Amino-acid	(1) Cell wall + protein	(2) Protein	(3) Cell wall	
Glycine	145	3	662	85
DL-Glutamic	17	3	65	33
L-Lysine	16	2	61	30

Washed cells were incubated for 1 hr. in phosphate buffer containing glucose (0·5 per cent), chloramphenicol (70 μgm./ml.) and 300 μgm./ml. of a labelled amino-acid, namely, glycine-1-^{14}C, or DL-glutamic acid-1-^{14}C or L-lysine (uniformly labelled). The specific activities of the amino-acids in the incubation medium were, respectively, 350, 665 and 1,350 counts/min./μ*M*. The cell fractions isolated were: (1) 'protein' (containing cell wall and 'true' cell proteins); (2) 'true protein'; and (3) cell wall. Specific activities of these fractions are given as counts/min. measured at infinite thickness

100° and hexosamines determined after treatment with a cation exchange resin ('Dowex 50') according to Boas[6].

Table 1 shows the type of results obtained when glycine, DL-glutamate and L-lysine labelled with carbon-14 have been present singly in the incubation medium. The greatest amount of cell-wall synthesis took place with glycine. It will be noted that, irrespective of the amount synthesized, virtually all the radioactivity was associated with the cell-wall fraction; the 'true protein' fraction contained only a trace of radioactivity. Omission of chloramphenicol from the incubation mixture did not substantially affect the results except that the radioactivity of the 'true protein' fraction was slightly increased.

The question now arises whether the incorporation of an amino-acid into the cell wall is the result of exchange between the amino-acid in solution and the corresponding residues in the wall, or whether it is due to an increase in the mass of the cell wall. In a typical experiment the specific activity of the glycine isolated from the cell wall indicated that an increase of 66 per cent should have occurred in the total amount of cell wall. This is in quite good agreement with the increase found in cell-wall mass (60 per cent). Using the hexosamine content of the 'protein' as a measure of the amount of cell wall indicated an increase of 52 per cent.

It thus seems certain that, in intact *Staphylococci*, cell-wall synthesis occurs in the presence of growth-inhibitory concentrations of chloramphenicol and that this is sufficient to account for the incorporation of glycine, glutamate and lysine into the 'protein' fraction. The incorporation of amino-acids into the 'protein' fraction of disrupted *Staphylococci* described by Gale and Folkes[7] has not been examined by us in this way, and it is, of course, possible that some process of exchange occurs in such preparations which does not occur in the intact cell.

'INTERCALATED' INTERNODES IN NERVE FIBRES

By Dr. L. LUBIŃSKA
Nencki Institute of Experimental Biology, Warsaw

In surveying teased nerve fibres from peripheral nerves of laboratory animals one sometimes encounters internodes which are much shorter and thinner than others on the same fibre. Such internodes were first observed by Rénaut[1] in peripheral nerves of horses and asses. Rénaut considered their existence as a proof that the nerve fibres grow not only from the central end but also by intussusception of new internodes and called them 'short intercalated segments'.

The short internodes probably represent a phase of restitution after a local inflammatory process described by Gombault[2] in lead poisoning and in many disorders of various origins. The process attacks individual internodes, or even portions of internodes, leading to granular destruction of myelin, and proliferation of Schwann cells in the affected region. The continuity of axoplasm is, however, usually preserved and the fibres do not degenerate. The denuded axoplasmic cylinder eventually becomes re-myelinated and recovers; the only permanent trace left is the shortness of newly formed internodes. Gombault calls this condition 'névrite segmentaire periaxile'.

The short internodes, vestiges of a local neuritis which struck some fibres at an earlier period, offer thus an uncommon opportunity to study the reorganization of a stretch of adult fibre after selective destruction of myelin. A short description of 'intercalated segments', based on an analysis of some forty peripheral fibres from fifteen cats, is therefore presented here.

The 'intercalated' segment always starts at a node and terminates at a node (Fig. 1). Sometimes a single short internode is present, more often the intercalated segment is formed by a succession of several short internodes. Various degrees of maturation are

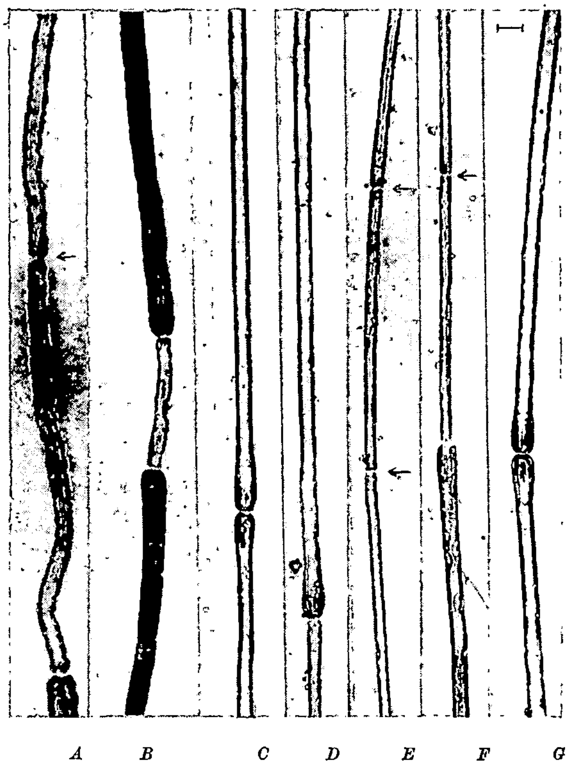

Fig. 1. 'Intercalated segments'. Proximal ends uppermost. Arrows indicate nodes between short internodes. Scale, 20μ. *A* and *B*, fibres fixed in osmium tetroxide; *A*, portion of an intercalated segment and junction with the distal normal internode; *B*, single short internode; *C* and *G*, normal portions of a fresh fibre containing four short internodes; *D*, *E* and *F*, consecutive portions of the intercalated segment

Table 1. NORMAL AND SHORT INTERNODES IN FIBRES OF CATS. SUCCESSIVE INTERNODES OF EACH FIBRE IN PROXIMO-DISTAL ORDER. ALL DIMENSIONS IN MICRONS

Fibre from	Internode	Total diameter	Axon diameter	Thickness of myelin	Location of the nucleus at	Length of the internode
Peroneal	I normal	19·8	11·7	4·0	880	1,750

	II normal	12·0	6·0	3·0	—	1,200
	III short	6·0	4·0	1·0	—	50
	IV normal	12·0	6·0	3·0	—	—

encountered. In some internodes the myelin is very thin and the amount of cytoplasm of the Schwann cell is increased. In others the myelin is much thicker and the excess of Schwann cell cytoplasm has already disappeared. The diameter of the axon is less than that of the normal internodes, both up and down the fibre, until the maturation of the short internode is fairly advanced.

When there are several short internodes in succession, the total length of the intercalated segment is similar to that of normal internodes of the same fibre, suggesting that a whole internode had been affected. The length of individual short internodes varies usually between 300 and 500μ. When a single short internode is 'intercalated' in the fibre, it is much shorter, rarely exceeding 50–150μ. Its length indicates that only a fraction of an internode had been involved in the neuritic process. At the junction with the short internode, the neighbouring normal ones end by bulbs of normal dimensions and shape characteristic of their proximal or distal location[3]. At least one of these bulbs is newly formed, showing that the end of the normal portion of the fibre has been reorganized.

The dimensions of normal and short internodes in several fibres are shown in Table 1.

The nucleus of the Schwann cell is always located in the middle of the short internode. This seems to indicate that the metabolic activity connected with the deposition of myelin extends in the Schwann cell symmetrically over a length of some 150–250μ on each side of the nucleus. If the denuded portion of axoplasm is longer, several Schwann cells adhere to it and the process of myelination starts in each cell, presumably by the mechanism elucidated by Geren[4] in developing fibres. Eventually several internodes are formed on a stretch occupied previously by one internode only. The length of new internodes is similar to that found by Vizoso and Young[5] in adult fibres regenerating after Wallerian degeneration and in fibres of very young animals.

In the early stages of restitution the nodes between successive short internodes are adumbrated simply by the interruption of myelin. The axon remains cylindrical throughout. It is only in the course of further maturation that the constriction of the axon at the node appears and the juxta-nodal bulbs develop.

The similarity in the behaviour of Schwann cells after a selective destruction of myelin and after Wallerian degeneration suggests that during the latter process it is also the breakdown of myelin, and not that of axoplasm, that determines the initial proliferation of Schwann cells. During the recovery the presence of the naked axon in the neurilemmal tube leads to a similar course of re-myelination and to similar morphological outcome in both conditions.

KINETICS OF HEAT INACTIVATION OF RIBONUCLEIC ACID OF TOBACCO MOSAIC VIRUS

By DR. WILLIAM GINOZA

Atomic Energy Project and Department of Radiology, School of Medicine, University of California at Los Angeles

IN marked contrast to the case of deoxyribonucleic acid, which is inactivated with a high-temperature coefficient[1] reminiscent of that of heat denaturation of proteins, it is found that loss of biological activity of the infectious ribonucleic acid of tobacco mosaic virus occurs with a moderate heat and a negative entropy of activation at neutral *p*H. The results are interpreted to mean that inactivation is a consequence of a single hydrolytic break in the phosphodiester backbone of the polynucleotide chain. The present findings, considered in the light of the known properties of this ribonucleic acid, indicate support for a single-stranded molecule.

Tobacco mosaic virus ribonucleic acid was obtained[2] by the method of Fraenkel-Conrat and Williams[3] from the common strain, *U*-1. Series of 0·1-ml. aliquots of a solution containing 1–2 mgm. of nucleic acid per ml. in 0·1 *M* phosphate buffer, *p*H 7·15, are heated for various periods at temperatures between 37° and 65° in a thermostatted water-bath. Heated samples and unheated controls are diluted to 10–30 μgm. per ml. in 0·067 *M* phosphate buffer, *p*H 7·0, and assayed on *Nicotiana glutinosa*, employing 20 half-leaves or more for any given sample. Under our conditions of assay, the lesion count response is linear with concentration of ribonucleic acid up to 30 μgm. per ml.

Results of a typical single experiment in which aliquots from the same nucleic acid preparation were heated at two different temperatures are shown in Fig. 1. It is seen that the plots of the logarithm of the surviving fractions versus time of heating are linear. While the error involved is inherently great in assays of this type, the results of numerous experiments indicate no systematic deviation from first-order kinetics. Heat inactivation of viruses in general follows a course of first-order kinetics ; numerous examples, including that of tobacco mosaic virus, are cited and discussed by Pollard[4]. The plot of the logarithm of the first-order rate constants versus the reciprocal of the absolute temperature is linear over the temperature-range 37°–65° (Fig. 2). The heats of activation ($\Delta H\ddagger$) and entropy of activation ($\Delta S\ddagger$) calculated from these data for the heat treatment leading to the loss in infectivity is about 19 kcal. per mol. and – 19·5 entropy units, respectively. Bacher and Kauzmann[5] obtained values which are very close to these from their experiments on the kinetics of hydrolysis of yeast ribonucleic acid. They followed the course of hydrolysis by titration.

From the moderate value of $\Delta H\ddagger$, it would appear that inactivation of tobacco mosaic virus ribonucleic acid does not involve disordering of secondary structure maintained by a large number of weak bonds, such as H-bonds. The negative entropy of activation observed is interpreted here to reflect the formation of a cyclic phosphate triester intermediate in the activated state of the molecule. It indicates that the activated molecule has less degrees of freedom because of the added bond between the phosphorus atom and the 2-OH of the ribose. A cyclic intermediate of this kind has been postulated by Fonó[6] and Brown and Todd[7] to explain the ease of hydrolysis of ribosephosphate as compared with that of deoxyribosephosphate. Bacher and Kauzmann[5] interpreted in this manner the kinetic data they obtained for the hydrolysis of yeast ribonucleic acid.

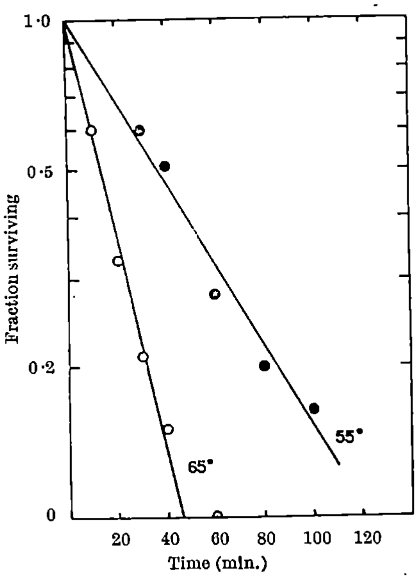

Fig. 1. Survival curves of tobacco mosaic virus ribonucleic acid heated at *p*H 7·15 in 0·1 *M* phosphate buffer

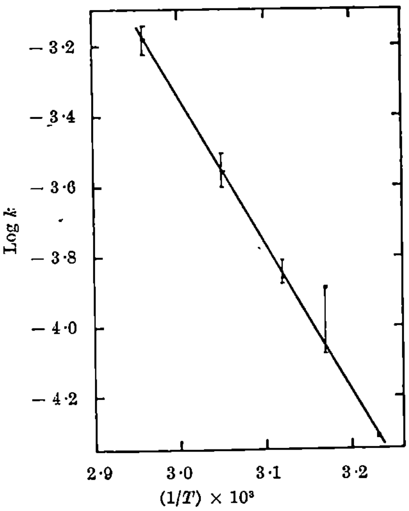

Fig. 2. Temperature dependence of the rate of inactivation of tobacco mosaic virus ribonucleic acid by heat at *p*H 7·15 in 0·1 *M* phosphate buffer. The rates at 37°, 42° and 47° were estimated from single point inactivation curves

The first-order kinetics observed in the heat inactivation of tobacco mosaic virus ribonucleic acid most likely means that a hydrolytic cleavage of only one phosphodiester bond is sufficient to inactivate the molecule. In this connexion, Gierer finds that the decrease in the mean molecular weight of tobacco mosaic virus ribonucleic acid is a simple exponential function of time of treatment with ribonuclease, suggesting that this molecule is single stranded[2,7]. Since hydrolysis of ribosephosphate bonds is involved in both cases, it follows that a single break in the polynucleotide chain by heat must also cause an exponential decrease in the mean molecular weight.

On the other hand, Thomas[8] finds that an enzymatic (deoxyribonuclease) breakdown of deoxyribonucleic acid is characterized by a lag, the molecular weight decrease being contingent on coincident rupture of two phosphodiester bonds, one on each of two chains and occurring within the distance of two nucleotides. Breaks occurring at greater distances from each other are not believed to result in scission of the deoxyribonucleic acid molecule because the intervening H-bonds are sufficiently strong to prevent separation of the two strands. Biological inactivation of bacteriophage labelled with phosphorus-32 has been studied by Stent and Fuerst[9]. In this case also the loss in biological activity is a consequence of breaks in phosphodiester bonds. A first-order kinetics is observed in this case as in that of tobacco mosaic virus ribonucleic acid, but their results are explicable only in terms of coincident scission of *both* strands of the deoxyribonucleic acid molecule. They conclude that where only a single break is incurred, the molecule is still capable of functioning. From these parallel observations, we are led to favour the view that tobacco mosaic virus ribonucleic acid is a single-stranded molecule. The comparative ease of hydrolysis of ribosephosphate bonds by heat, together with its single-stranded structure, could well account for the widely observed tendency of tobacco mosaic virus ribonucleic acid and ribonucleic acid from other sources to depolymerize rather readily[10-13].

The values of $\Delta H^\ddagger$ and $\Delta S^\ddagger$ derived from the present kinetic studies indicate that there is also a marked dissimilarity between tobacco mosaic virus ribonucleic acid and the deoxyribonucleic acid transforming principle of *Hemophilis influenzae* with respect to response to heat[14]. With deoxyribonucleic acid, the rates of biological inactivation and loss of viscosity due to heat are not measurable until a critical temperature of about 80° C. is reached ; but the rates for both changes become great above this temperature. In confirmation of the work of Zamenhof *et al.*, Doty has obtained values of 93 kcal. per mol. and 220 e.u. for the energy of activation and entropy of activation, respectively, for the heat denaturation of deoxyribonucleic acid as measured by change in viscosity[1]. This change is not accompanied by change in molecular weight. These high values are interpreted in terms of the breaking of about fifteen successive pairs of H-bonds in the Watson–Crick structure in the activated state which precedes the irreversible collapse of the molecule. The same high order of $\Delta H^\ddagger$ and $\Delta S^\ddagger$ can be estimated from the kinetics of the loss both in the transforming activity and in the viscosity of *H. influenzae* deoxyribonucleic acid from the data of Zamenhof *et al.* Both changes are found to commence at the same temperature[14]. Thus, the kinetic studies suggest that heat inactivates deoxyribonucleic acid by a process akin to protein denaturation, whereas it inactivates tobacco mosaic virus ribonucleic acid by a breakage of a covalent bond with a direct loss in molecular weight.

The following properties of tobacco mosaic virus ribonucleic acid further point to its difference from the Watson–Crick structure : (1) the purine-to-pyrimidine ratio deviates from unity ; Knight's data show the ratio[15] is 1·2 ; (2) the sign of birefringence is positive in the case both of the free nucleic acid[16] and of the intact virus[17], indicating that the bases are aligned parallel to the long axis of the molecule, while the sign is negative in the case of deoxyribonucleic acid[18] ; (3) tobacco mosaic virus ribonucleic acid reacts readily with formaldehyde[19] and is adsorbed by active carbon[20]. Both of these reagents do not affect deoxyribonucleic acid because the bases with which they presumably interact are inside the coaxial helix. The bases of the ribonucleic acid molecule must be in some situation easily accessible to these reagents. Thus, the two important requirements—base composition and conformation—upon which the specific hydrogen-bonding of the two-stranded helix of deoxyribonucleic acid depends are shown not to be satisfied by tobacco mosaic virus ribonucleic acid.

The present comparative studies of the kinetics of degradation by heat and enzymes and of other physical and chemical properties indicate that tobacco mosaic virus ribonucleic acid is quite unlike that of the Watson–Crick double helix. These studies are of particular interest because tobacco mosaic virus ribonucleic acid and deoxyribonucleic acid molecules both share a common biological function, namely, that of self-replication. This interest is reflected in the current investigations dealing with the question of whether synthetic polyribosenucleotides can form copolymers truly resembling the structure of deoxyribonucleic acid[21,22]. There appears to be no evidence, however, to suggest that any of the naturally occurring ribonucleic acids, including that of tobacco mosaic virus, is double stranded.

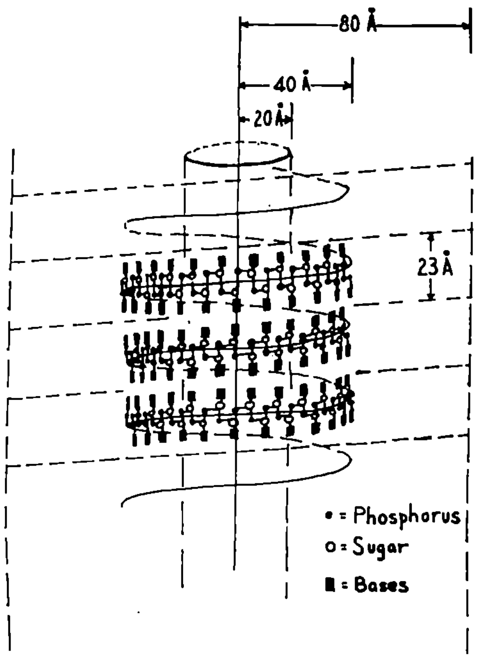

Fig. 3. Schematic representation of a single-strand nucleic acid helix of 40-A. radius (ref. 29) in position within the tobacco mosaic virus rod. The spacings of the purine and pyrimidine bases, ribose rings and phosphorus atoms with respect to the helix are made approximately to scale. There are about 50 bases per turn of the helix, aligned parallel to the longitudinal axis of the virus particle. A central hole of 20-A. radius extends the length of the particle. A protein matrix of 60-A. radius or thickness (80-A. radius of the virus less 20-A. radius of the hole) is composed of a few thousand equivalent sub-units set in a helical array about the axis of the rod (ref. 23)

Franklin *et al.* suggest that one possible model of tobacco mosaic virus ribonucleic acid involves a single strand coiled the length of the virus rod in structural conformity to the protein helix[23]. A diagram of the nucleic acid can be drawn (Fig. 3) embodying this suggestion as well as the dimensions obtained from the X-ray studies by Franklin[24] and by Casper[25] on the intact virus and its substructures. That the strand is a single molecule with a weight of about 2 million is indicated by the work of Hopkins and Sinsheimer[26], Ginoza and Norman[13] and Gierer[27]. The orientations of the ribose, phosphate and bases are arbitrarily patterned after Furberg's deoxyribonucleic acid model II[28]. The diagram depicts the ribose rings and the phosphorus atoms to be in one plane as a ribbon-like structure wound with a pitch of 23 A. (pitch of the protein helix[24]) to form a cylinder of 40-A. radius[29] by 3000-A. length[30]. The length of a helix calculated from these dimensions is about 33,000 A. For a nucleic acid chain of molecular weight 2 million to conform with this length, the spacings between phosphorus atoms along the helix would have to be about 5 A.—a reasonable value[31]. The radii of the central hole and of the virus are 20 A. and 80 A., respectively[25]. The planes of the bases are aligned, as required by the positive sign of birefringence[16,17], parallel to the long axis of the helix. A structure coiled in the manner depicted can account for the sign, which is the opposite of that reported for other ribonucleic acids[32] and deoxyribonucleic acid[18]. The 'open' arrangement of these bases is consistent with their known reactivity with formaldehyde[19] and adsorbability on active carbon[20]. The fact that this nucleic acid in cold solution will retain its positive birefringence[16] as well as its biological activity for some days following its isolation from the virus suggests that there is some kind of force stabilizing the helix. Under the present scheme, a single-chain polymer free in solution may be stabilized, as Gierer also suggests, by hydrogen bonds between turns of the helix. Such bonding would require or lead to some contraction of the coiled molecule, because the 23-A. spacings between turns would be too wide for the bridging. This type of interaction, however, is not expected to be comparable in magnitude or specificity with that involved in the internucleotide hydrogen-bonding of the deoxyribonucleic acid molecule. In the intact virus particle it appears unnecessary to invoke hydrogen-bonding to stabilize the helix because the protein matrix would be expected to perform this function.

I gratefully acknowledge the helpful discussions and criticisms of Drs. Amos Norman, Benedict Cassen, David R. Howton and Edward Carusi. I am also indebted to Carol J. Hoelle for technical assistance and to Dr. Samuel G. Wildman for the generous support of this work.

DEPENDENCE OF THE OBSERVED OXYGEN EFFECT ON THE POST-IRRADIATION TREATMENT OF MICRO-ORGANISMS

University College of Science
PHYSICS Dept.
92, Upper Circular Rd., Calcutta

By TIKVAH ALPER and DR. N. E. GILLIES

Medical Research Council Experimental Radiopathology Research Unit, Hammersmith Hospital, London, W.12

TWO commercially available complete media, 'Oxoid Blood Agar Base' (10 gm. 'Lab Lemco', 10 gm. 'Oxoid' peptone, 5 gm. sodium chloride, 15 gm. agar/l.) and 'Difco Bacto Nutrient Agar' (3 gm. 'Bacto' beef extract, 5 gm. 'Bacto' peptone, 15 gm. 'Bacto' agar/l.), have been used in investigations concerning the sensitivity of *Escherichia coli, B* to ionizing and ultra-violet radiation. Survival after irradiation was estimated by plating samples, after each dose, on both 'Difco' and 'Oxoid' plates, and counting colonies after 15–24 hr. incubation. Survival curves plotted from the plate counts were always of different slope, being steeper for counts made on the 'Oxoid'. The ratios of the slopes varied from about two to more than six, depending on the type of radiation and the handling of the bacteria before irradiation (Figs. 1 and 2). After treatment by exposure to heat (51° C.) or to 0·6 per cent phenol, however, surviving fractions were the same on the two media.

Since fewer organisms formed colonies on 'Oxoid' than on 'Difco' agar, after a given dose of radiation, two possibilities were envisaged: first, that the 'Difco' medium might contain a higher concentration of growth factors for which the radiation had induced a special requirement, or secondly, that the 'Oxoid' medium contained factors which inhibited colony formation by the irradiated bacteria. The second alternative was found to be the correct one. Dialysable substances were found to be present in the 'Oxoid' nutrients which, when added to 'Difco' agar, caused the viable counts to be reduced to those observed on 'Oxoid' plates. One of these substances has been identified as chloride ion; the other, not yet identified, is associated with peptone which is present in higher concentration in the reconstituted 'Oxoid' medium. The evidence for these conclusions will be dealt with in detail elsewhere.

The results indicate that a particular type of radiation damage becomes apparent only when the bacteria are plated on a medium containing these dialysable substances, so that on other media the bacteria 'recover' from part of the total radiation effect. Our results resemble those of Roberts and Aldous[1], who plated *E. coli, B* after irradiation on synthetic and on nutrient agar, and found much the same relationship between viable counts on these two media, after ultra-violet irradiation, as we have found with 'Difco' and 'Oxoid' agar. They concluded that the nutrient medium contained a factor responsible for bringing to light a part of the damage which did not appear when a synthetic medium was used. Roberts and Aldous, however, found no effect of medium on *E. coli, B* after X-irradiation.

The presence of oxygen increases the lethal effects of ionizing radiations on bacteria[2], but does not modify the effect of ultra-violet light (Alper, unpublished results). However, that part of the damage to *E. coli, B* which is medium-sensitive appears to be much less affected by the presence of oxygen than the part of the damage which is not medium-sensitive. Thus the medium effect on a washed suspension of stationary-stage *E. coli, B* was greatest with ultra-violet light, less with X-rays in anoxic conditions, and least with X-rays under oxygen. On the other hand, the enhancement by oxygen of the sensitivities to ionizing radiations (X-rays and neutrons) was considerably greater when the bacteria were plated on 'Difco' than when they were plated on 'Oxoid'.

Radiosensitivity (S) may be defined as the inverse of the dose (D) necessary to reduce the population of colony-forming bacteria to a given fraction of the controls. If it is correct to regard the medium-sensitive and the oxygen-sensitive parts of the damage as separable, then in the general case

$$S = m\Sigma\lambda m + \Sigma\lambda n$$

where λm represents components which in the presence of oxygen are increased by a factor m, while λn represents components not modifiable by oxygen. It will be assumed that with *E. coli, B* plated on 'Difco' agar the observed radiosensitivity itself contains components which are not modifiable by oxygen, so that

$$S_{Difco} = m\,\lambda_1 + \lambda_2$$

The extra sensitivity apparent from the action of the dialysable substances from 'Oxoid' medium will be denoted by λ_{ox}.

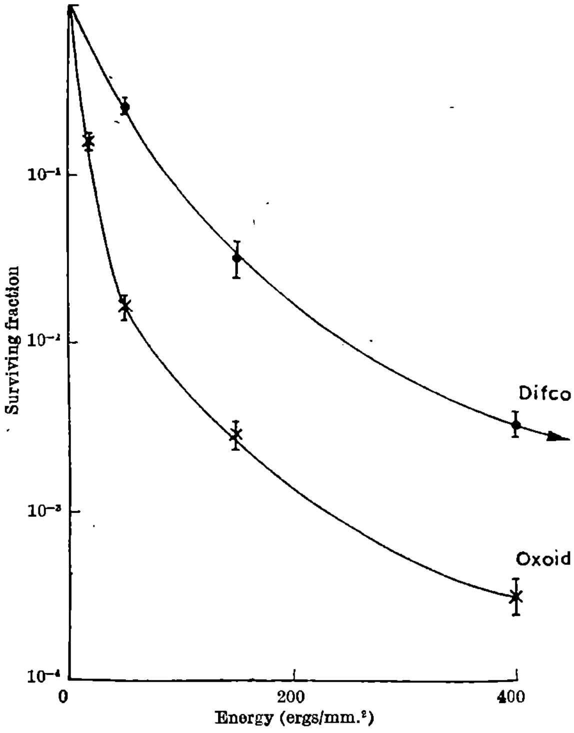

Fig. 1. Survival of *E. coli, B* in the stationary phase, after exposure to ultra-violet light

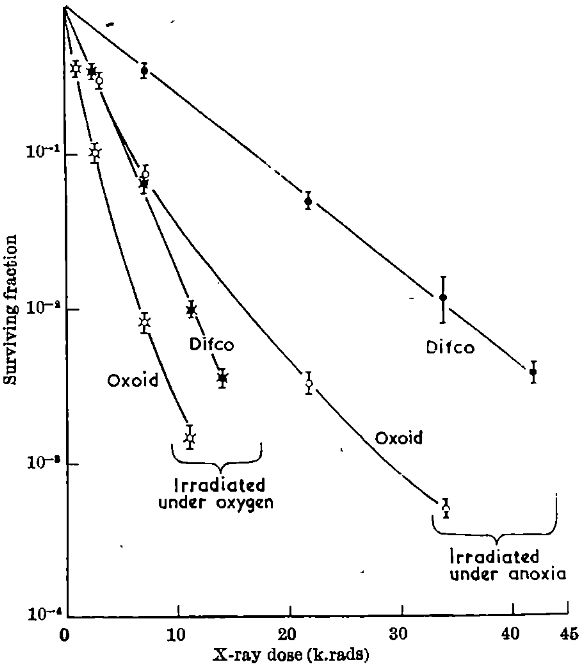

Fig. 2. Survival of *E. coli, B* in the stationary phase, after exposure to X-rays under oxygenation and anoxia

There are then four cases:

$$\text{With anoxic irradiations}\left\{\begin{array}{l} S_{Difco} = \lambda_1 + \lambda_2(\propto 1/D_1) \\ S_{Oxoid} = \lambda_1 + \lambda_2 + \lambda_{ox}(\propto 1/D_2) \end{array}\right.$$

$$\text{Irradiations with oxygen present}\left\{\begin{array}{l} S_{Difco} = m\lambda_1 + \lambda_2(\propto 1/D_3) \\ S_{Oxoid} = m\lambda_1 + \lambda_2 + \lambda_{ox}(\propto 1/D_4) \end{array}\right.$$

It would follow that

$$\frac{1}{D_1} + \frac{1}{D_4} = \frac{1}{D_2} + \frac{1}{D_3}$$

The doses found necessary to reduce the survivors of a suspension of *E. coli, B* to 10 per cent of the controls, with both X-rays and neutrons, are given in Table 1.

Table 1

Plating medium	Irradiated suspension	Symbol for dose to give 10 per cent survival	X-ray dose (k.rads)	Neutron dose (88 per cent neutrons, 12 per cent X-rays) (k.rads)
'Difco'	anoxic	D_1	16·8	8·8
'Oxoid'	,,	D_2	6·0	3·8
'Difco'	oxygenated	D_3	5·8	5·2
'Oxoid'	,,	D_4	2·9	2·6

For X-rays,

$$\frac{1}{D_1} + \frac{1}{D_4} = 0{\cdot}40$$

$$\frac{1}{D_2} + \frac{1}{D_3} = 0{\cdot}34$$

For neutrons,

$$\frac{1}{D_1} + \frac{1}{D_4} = 0{\cdot}49$$

$$\frac{1}{D_2} + \frac{1}{D_3} = 0{\cdot}47$$

For both types of radiation the agreement is within the limits of the errors involved in the determination of the doses required to give 10 per cent survival.

The relative radiosensitivities of test materials irradiated in the presence and in the absence of oxygen are of great theoretical importance. It is worth emphasizing, therefore, that the observed magnitude of this ratio for *E. coli, B* is dependent on the plating medium chosen. With 'Difco', the ratio of radiosensitivities to X-rays was observed to be $16{\cdot}8/5{\cdot}8 = 2{\cdot}9$ (given by $(m\lambda_1 + \lambda_2)/(\lambda_1 + \lambda_2)$, in the symbols defined above), whereas with 'Oxoid' as the plating medium the ratio was observed to be

$$\frac{6{\cdot}0}{2{\cdot}9} = 2{\cdot}1, \text{ given by } \left(\frac{m\lambda_1 + \lambda_2 + \lambda_{ox}}{\lambda_1 + \lambda_2 + \lambda_{ox}}\right)$$

It can be predicted that if a medium is used which will reduce λ_2 to less than its value with 'Difco', a still greater ratio of 'oxygenated' to 'anoxic' radiosensitivities will be observed.

The following bacteria have also been tested for survival after irradiation on 'Difco' and 'Oxoid' plates: *E. coli, B/R*; *E. coli, K*12; *E. coli*, 86; *Shigella flexneri, Y6R*; and *Salmonella typhimurium*. Only the last-mentioned showed an effect similar to that shown by *E. coli, B*, and this to a much smaller extent. However, post-irradiation modification of damage to various micro-organisms by different methods have been reported[3], and there are indications that effects may be found with other species which are analogous to those which occur with *E. coli, B*. It seems likely, therefore, that the extent of the oxygen effect observed with strains other than *E. coli, B* might be modified by the post-irradiation treatment. Such phenomena may be in part responsible for different oxygen enhancement ratios observed with closely related strains of micro-organisms[4], or for different ratios observed with the same strains in different laboratories.

We are greatly indebted to Mr. D. Moore for carrying out the neutron irradiations and dosimetry.

INFRA-RED SPECTRA OF FREE RADICALS

By Dr. K. NOLEN TANNER* and RAYMOND L. KING

U.S. Naval Ordnance Laboratory, Corona, California

FLASH photolysis has been extensively used to produce momentarily a sufficiently high concentration of a number of free radicals to enable their absorption spectra to be observed in the photographic regions[1-4]. The availability of photoconductive detectors with time constants of the order of 10 μsec. or less makes it possible to examine fast reactions in the infra-red, and several rapid-scanning infra-red spectrometers have been designed and constructed for this purpose[5,6]. We have constructed such an instrument with a lead telluride detector and have used it to search for the N–H stretching frequencies of the NH_2 molecule.

The instrument is equipped with a calcium fluoride prism and uses a continuously rotating Littrow mirror. The mirror is aluminized on both sides and sweeps a spectrum across the exit slit twice in each rotation. An 'optical vernier' system supplies a set of fiduciary marks which enable the angular displacement of the mirror to be measured with a precision somewhat better than ½′. The spectrum and the markers are presented on the two traces of a DuMont Type 322*A* double-beam oscilloscope. The first marker in the set synchronizes the oscilloscope sweep and the high-intensity photolysis flash.

The flash is produced in the usual manner[3] in a quartz tube 1 m. long and 1 in. in diameter inside a cylindrical reflector adjacent to a quartz absorption cell 1 m. long and 2 in. in diameter. The spectrum source is a tungsten filament or Nernst glower forming an image on the entrance slit.

When hydrazine is photolysed at a pressure of about 1·2 cm. and with a flash energy less than 3,000 joules, the 3-μ doublet becomes rather ragged on the long wave-length side, but is otherwise unchanged. At flash energies of 3,000 joules and more, the explosive thermal decomposition of hydrazine is triggered[8]. The doublet disappears and is replaced by a broad region of absorption between slightly less than 3·00μ and about 3·24μ. The spectrum taken several seconds after the flash shows only the *Q*-branch of the NH_3 produced, with a shoulder on the long wave-length side due to undecomposed hydrazine.

Fig. 1 shows tracings of a typical sequence of records for a photolysis experiment. *A* is the comparison spectrum of hydrazine recorded several seconds before the flash is triggered; *B* is the flash record itself. The oscilloscope sweep, initiated simultaneously with the flash, was started at the point marked *X* and was carried off the face of the oscilloscope by the scattered light and the accompanying electric and electromagnetic noise pulse. Recovery was complete in 0·5–0·6 msec. *C* is the spectrum of ammonia and residual hydrazine, products of the reaction, taken several seconds after the flash. *D* is the set of fiduciary marks recorded with *C*. The markers recorded with the other traces have been omitted. *E* is a set of time markers recorded immediately after *C* by substituting in the spectrum channel the output from a 'Tektronix' Type 180 time-mark generator. The oscilloscope sweep has been expanded about three-fold and becomes somewhat non-linear at the edges, but this does not interfere with either the measurement of wave-length or time interval. The markers shown are at 0·1- and 1·0-msec intervals.

A number of such sets of records have been obtained, and, in general, the successive traces in a set can be reasonably well superimposed except in the regions

---

[*] Present address: Department of Ophthalmology, University of Oregon Medical School, Portland, Oregon.

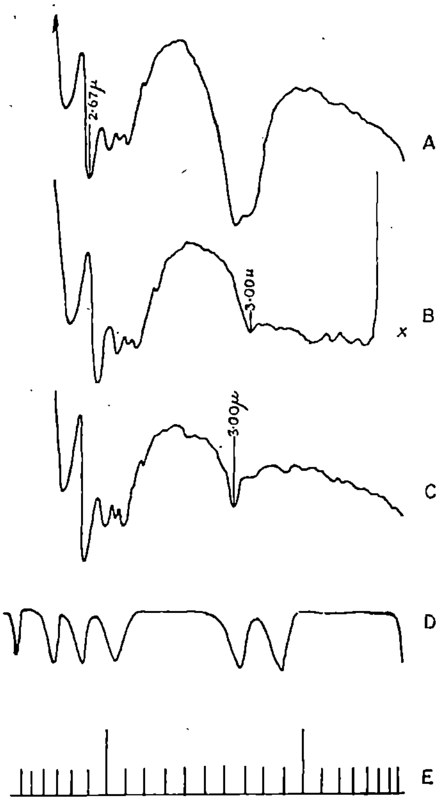

Fig. 1. Tracings of a typical record sequence. (*A*) Initial spectrum of parent compound (hydrazine). (*B*) Flash spectrum showing free-radical absorption. The spectrum is swept from right to left. (*C*) Product spectrum taken several seconds after the flash showing ammonia and residual hydrazine bands. (*D*) Fiduciary marks recorded simultaneously with *C*. (*E*) 1·0 and 0·1 msec. time marks recorded several seconds after *C*

of differing absorption and at the extreme ends. Using the final NH_3 spectrum as a background except in the 3-μ NH_3 band itself where the background was interpolated from the band edges, several records have been reduced to per cent transmission plots which are shown in Fig. 2. (In each case the abscissa is that of the original record and has not been reduced to a common linear wave-length scale; however, the measured wave-lengths are given.) It is noted that in every case a definite band appears at 3·125 ± 0·01μ. The 'fine structure' observed on one trace is probably a noise artefact. The time marks make it possible to determine the interval between the initiation of the flash and the appearance of the 3·125-μ band at the exit slit. These time intervals are given in Fig. 2. It is evident that the 3·125-μ band becomes progressively weaker and the 3·00-μ NH_3 band becomes stronger as the time between the flash and the passage of the band across the exit slit increases. It appears then that the absorption at 3·125μ is due to a transient molecule with a half-life somewhat less than 1 msec., but which can still be observed several milliseconds after the initiation of the flash. This corresponds with the kinetic behaviour of the α-bands ascribed by Herzberg and Ramsay to the NH_2 molecule[7,8].

There are two N–H stretching frequencies for this molecule in the 3-μ region, and if the force constants are not too different from those of NH_3, the symmetric stretching frequency, ν_1, will be at about 3·1μ and the unsymmetric frequency, ν_3, rather close to 3·0μ (ref. 7). It is impossible from the present records to distinguish unambiguously this latter band from that of NH_3. Nevertheless, it is evident that there is strong absorption between 3·0 and 3·1μ. Part of this absorption remains on the spectrum taken several seconds after the flash, and is evidently due to hydrazine. This might be expected as arising from the recombination of NH_2 radicals. However, the absorption intensity in this region is strong relative to the NH_3 band at 3·0μ immediately after the explosion, and the intensity decreases in much the same way as that of the 3·125-μ band. From an average of several estimates of the maximum absorption in this region immediately after the flash, the ν_3 band of NH_2 has been assigned the wave-length 3·049μ (3,280 cm.$^{-1}$). Using the assignments of ν_1 = 3,200 cm.$^{-1}$ (3·125μ), ν_3 = 3,280 cm.$^{-1}$ (3·049μ), and 103° as the valence angle[9], we have calculated the valence force constants[10] as k_l = 5·74 × 10^5 dynes per cm. and k_δ/l^2 = 0·31 × 10^5 dynes per cm. These values fall into the general pattern of force constants observed for other XY_2 molecules and for NH_3. The bending frequency ν_2 calculated from the simple valence force treatment has the value ν_2 = 1,060 cm.$^{-1}$ (9·4μ).

In addition to the NH_2 spectrum, Ramsay[8] observed NH bands. The absorption in the 3-μ region of the exploding gas is quite general, and absorption from NH molecules can certainly be accommodated in the observed spectrum. However, the band of the NH molecule at the high temperatures would be expected to be rather wide and relatively weak at the centre, whereas the two NH_2 bands, and particularly the ν_3 band, are expected to be more compact.

The possibility suggests itself that the absorption might be due to 'hot' molecules, either N_2H_4 or NH_3, and it is true that absorption from such species would be expected in this region. The rotational temperature observed by Ramsay[8] for NH radicals in the explosive decomposition of hydrazine is 1,400° K. Hydrazine decomposes thermally at a temperature of 250°–300° C. (ref. 11), and explodes at a much lower temperature when sparked. It seems unlikely that at 1,400° K. the molecule would last as long as a few microseconds, about 10^7 vibrational cycles, without decomposing. However, the principal argu-

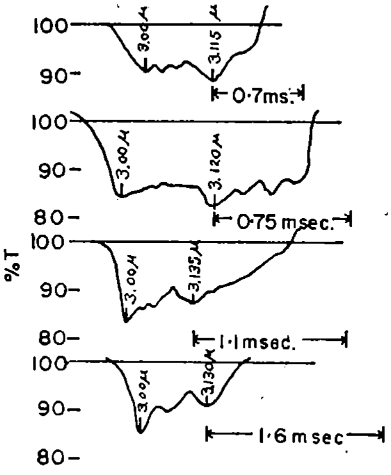

Fig. 2. Four flash spectra plotted as per cent transmission showing measured wave-lengths and delay times

ment against the assignment of these bands to either 'hot' N_2H_4 or NH_3 is the kinetic one. The maximum absorption of the transient band is about 0·75 msec. after the initiation of the flash, or about 0·6 msec. after the peak of the flash intensity. As the transient absorption decays, the 3-μ ammonia band grows at about the same rate. There is no period either before the appearance of the transient band or between it and the appearance of the NH_3 band which would accommodate an intermediate compound with a half-life anything like 1 msec. But Ramsay and Herzberg have convincingly demonstrated the presence of NH_2 radicals with a half-life of about 1 msec. in this system. The 'hot' molecule hypothesis then necessarily implies that: (1) the principal quantity of hydrazine is converted directly to ammonia without the formation of an intermediate compound with a half-life greater than a fraction of a millisecond other than the 'hot' molecule itself; and (2) that the NH_2 absorption coefficients are exceptionally small in the infra-red or exceptionally large in the violet. Neither of these implications is inherently plausible, nor is the first in accord with the postulated mechanisms of the reaction[11].

Ramsay and Herzberg[7] observed the NH_2 spectrum in the flash photolysis of 1 mm. of NH_3 ". . . with approximately the same intensity . . ."[8] as observed in the explosive decomposition of hydrazine. A considerable effort has been made to observe the 3·125-μ band in the photolysis of ammonia and in the non-explosive (using sub-critical flash energy) photolysis of hydrazine. The results have been uniformly negative. In the case of NH_3, this is not too surprising, since the decomposition of NH_3 requires light with a wave-length shorter than about 2100A., and a relatively small proportion of the flash energy will be in this region. Hydrazine photolyses on irradiation at somewhat longer wave-lengths. Fig. 2 shows that the maximum optical density in the transient absorption is about 0·08. A reduction in partial pressure by a factor of ten would take the signal into the noise-level. When the α-bands are observed with photographic plates, however, the more or less linear relationship between the photographic density and the logarithm of the incident intensity would make the method much less sensitive to changes in optical density at very weak absorption-levels. In fact, if the plates were developed so that the zero absorption background still lay on the 'toe' of the characteristic curve, the increasing gamma for larger transmitted intensity (weaker absorption) would tend to suppress to the eye the effects of decreased radical concentration. Infra-red absorption coefficients are considerably smaller than those for electronic-vibration bands, so it appears to be evident that the flash alone simply does not supply enough effective photons to create an observable concentration of these radicals in the infra-red.

Norrish *et al.*[2,4] have photographed the ultra-violet spectra of a number of diatomic free radicals produced in explosions initiated homogeneously throughout the absorption cell by free radicals resulting from the flash photolysis of nitrogen dioxide or a similar sensitizing compound. Plots of the measured concentrations against the time from the initiation of the flash show a characteristic sharp rise in 0·1–0·6 msec., followed by a slower decay. Fig. 3 shows a similar situation for the present 3·125-μ absorption. The open rectangles give the measured absorption intensity relative to the original N_2H_4 intensity vs. the time in milliseconds after the initiation of the flash. The areas of the rectangles indicate the probable error limits of the measurements. The crossed square is the result of an experiment in which the 3·125-μ band was obscured by the flash, but no, or at most very little, absorption could be observed at 3·00μ 0·6 msec. after the flash. Electronic recovery was essentially complete at this wave-length at about 0·5 msec. Since little or no absorption was observed which could be ascribed to ammonia, the reaction product, or to the 3·05-μ (or vicinity) NH_2 band, it has been assumed that the absorption at 3·125μ is zero or almost zero. Another experiment, in which the 3·125-μ band was obscured by the flash but the 3-μ region was not, showed a small but definite absorption at 3·00μ at about 0·7 msec. The solid line curve is a logarithmic decay curve obtained by fitting by eye a straight line to the points on a semilog plot. The half-life is 0·7 msec. A record in which the 3·125-μ band was scanned at 4 msec. showed no detectable absorption. The NH_3 bands at 3μ were somewhat broadened, but otherwise the same as those scanned several seconds after the flash.

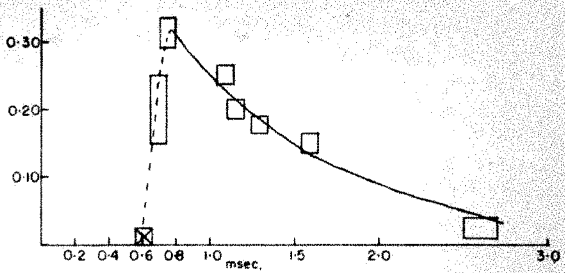

Fig. 3. Relative absorption intensity versus time after initiation of photolysis flash. Solid curve is logarithmic with a half-life of 0·7 msec.

While not completely unambiguous, until high resolution can be applied to these bands, the best interpretation appears to be that they are principally due to NH_2 radicals with possible contributions from NH, N_2H_3, and 'hot' N_2H_4 and NH_3.

It has been shown that with the use of fast photoconductive detectors, infra-red spectroscopy can be applied to the study of free radicals and other short-lived molecules with conditions of resolution approaching those of conventional instruments using thermal detectors. Furthermore, by direct photometric techniques, kinetic studies can be made easily and relatively accurately.

Work on the spectra of other free radicals and a more complete description of the apparatus will be published elsewhere.

This investigation has been conducted under the sponsorship of the United States Air Force, Office of Scientific Research.

Early Stages of Infection with the *Tipula* Iridescent Virus

In previous studies on this interesting virus, empty membranes of the same size and shape as the virus particle were frequently seen. The possibility was envisaged[1] that these empty membranes might be incomplete virus particles analogous with the nucleic-acid-free 'top component' of the turnip yellow mosaic virus[2].

Further work, however, with ultra-thin sections of fat-body from infected larvæ of *Tipula paludosa* suggests an alternative explanation. Examination of material in the early stages of infection reveals the presence of these empty membranes in very large numbers; they are often more numerous than the normal virus particles (Fig. 1). Furthermore, they do not seem to occur in the advanced stages of the disease in which the virus particles are lining up to form microcrystals in the fat-body; in such a case all the virus particles are fully formed.

In addition to the completely empty membranes, others occur with a small dark central spot, varying in size in different membranes. It is, in fact, easy to pick out all the stages in which the size of the central spot varies, from the first beginnings to the completely filled membrane of the mature virus particle (Fig. 2).

It seems, therefore, a reasonable assumption that these empty and partly empty membranes may be stages in the development of the *Tipula* iridescent virus. This is further supported by the fact that they do not apparently occur in the late stages of the disease. Because these empty forms are the same size as the fully formed virus particle, the possibility is ruled out that the appearance is due to an oblique

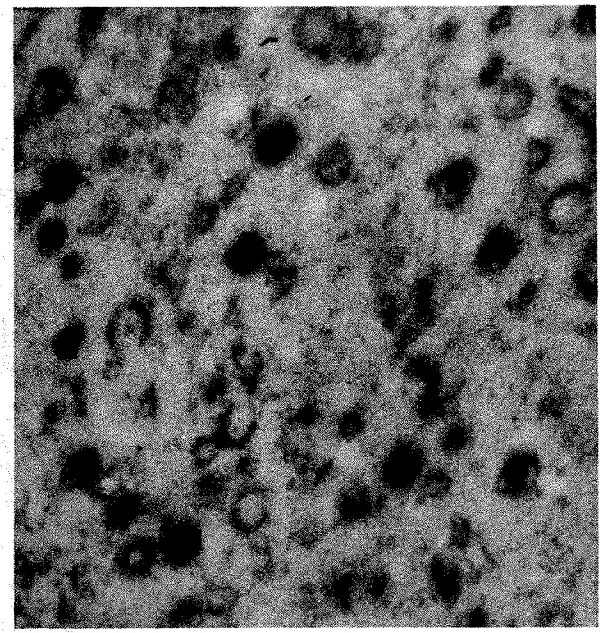

Fig. 1. Ultra-thin section of *Tipula* fat-body showing numerous empty membranes; virus particles appear dark. (× 40,000)

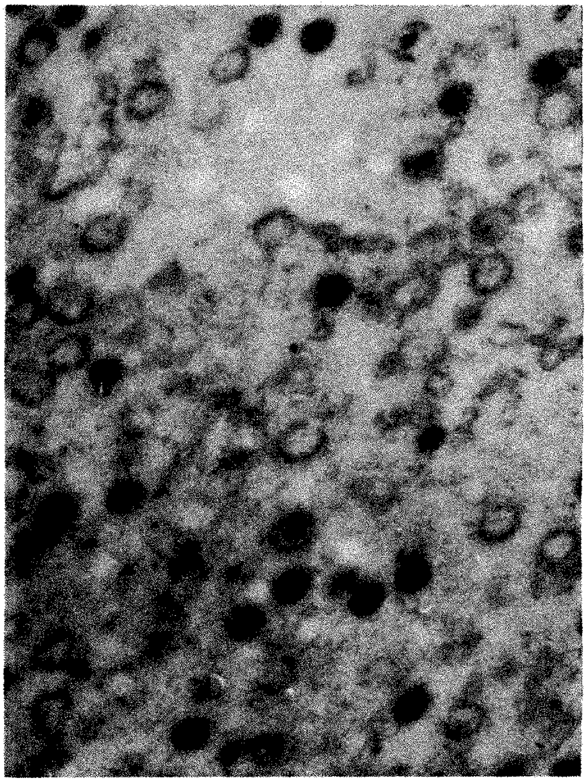

[Fig. 2. Similar to Fig. 1, but showing several membranes with a developing centre. (× 40,000)

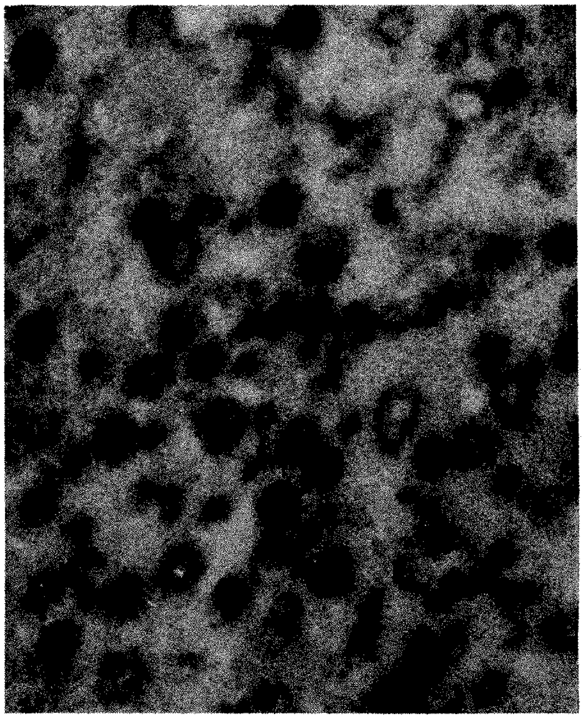

Fig. 3. Similar to Fig. 1, but showing the resemblance between the virus membranes and the endoplasmic reticulum. (× 40,000)

section passing through part of the particle only. On this assumption, the process seems to be that the membrane forms in the cytoplasm first, and then the deoxyribonucleic acid and protein begin to appear as a small darkly staining spot in the centre gradually increasing in size until the membrane is filled.

Another rather striking fact, which may of course be coincidental, must be pointed out. This is the truly remarkable resemblance between the empty virus membrane and the endoplasmic reticulum[3]. The diameter and appearance of the limiting membranes appear identical and here again all grades exist between the long forms and the oval-shaped membranes of the endoplasmic reticulum; these latter cannot be differentiated on the electron microscope from the empty virus membranes (Fig. 3).

I am indebted to Mr. G. J. Hills for taking the electron micrographs.

Influence of Cocarboxylase on Tolerance to Morphine in the Rat

THE basic physiological mechanism affected by morphine may be that of the enzymatic processes involved in glucose metabolism: it is known, indeed, that morphine inhibits glucose and pyruvic acid utilization by minced brain[1], and the decarboxylation by rabbit's liver and brain homogenates of pyruvic acid[2]. Further, morphine is known to reduce the level of carbon-14 in brains of rats fed with labelled glucose[3]. Cocarboxylase activity is unaffected in chronically morphinized rats, but responses to pyruvate and cocarboxylase of *in vitro* muscle from animals deficient in thiamine and from chronically morphinized ones are similar, suggesting a metabolic defect in common to both conditions[4]; thiamine has no effect on morphine withdrawal symptoms in man[5], though it decreases their intensity in rats[6]. Lastly, glycids and their metabolites change the analgesic effect of morphine.

We therefore investigated the influence of thiamine and of cocarboxylase on the analgesic effect of morphine and on the appearance of tolerance to this effect.

Ninety rats were used in three sets of experiments. The animals, after a control analgesimetric test for a standard dose of morphine, were treated daily with thiamine or cocarboxylase followed 30 min. later by morphine. Controls received daily morphine only. In the course of treatment analgesimetric tests were carried out about every ten days. The analgesic effect of morphine was determined by the D'Amour and Smith technique and the analgesic efficacy was estimated in minutes and seconds of analgesia[7]. Table 1 shows the scheme of treatment in each set of experiments, and Fig. 1 shows the results.

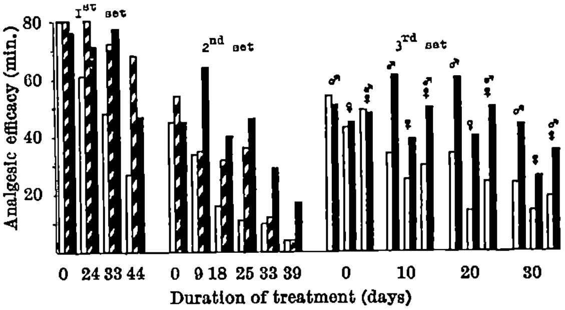

Fig. 1. Analgesic efficacy of a standard dose of morphine in successive tests in control animals and in animals pretreated with thiamine or cocarboxylase during chronic treatment with morphine. Open columns, controls; diagonally shaded columns, pretreated with thiamine; black columns, pretreated with cocarboxylase

In our experimental conditions, daily treatment with thiamine or cocarboxylase at first prevented and afterwards delayed—in comparison with the controls—the progressive appearance of tolerance to the analgesic effect of morphine. In these conditions we were not able to detect any analgesic effect due to thiamine or cocarboxylase, or any potentiating effect, in a merely pharmacological sense, of the analgesic effect of morphine. The main observations were as follow:

(*a*) With the progressive appearance of tolerance to the analgesic effect of morphine, the behaviour of the control animals changes; they become hyper-excitable, hyper-reactive and aggressive. This does not happen with the animals pre-treated daily with thiamine or cocarboxylase until the analgesic response remains unchanged or moderately decreased. Tolerance and change in behaviour may, therefore, be connected.

(*b*) The abrupt interruption of the daily morphine treatment in the controls—once tolerance to the analgesic effect has appeared—induces on the following day a moderate state of depression. This does not happen with animals pre-treated with thiamine or cocarboxylase.

(*c*) Instituting treatment with cocarboxylase in controls which have become tolerant to the analgesic effect seemed to accelerate the rate of recovery of the analgesic response to morphine.

Table 1. SCHEME OF TREATMENT

		No.	Weight (gm.)	Sex	Test morphine (mgm./kgm. subcutaneous)	Treatment (10 mgm./kgm. intraperitoneally)	Morphine		Time (days)
							Route	mgm./kgm./day	
1	Controls Pretreated Pretreated	10 10 10	130–200	♂ and ♀ (random)	10	Sodium chloride 9°/₀₀ Thiamine Thiamine + cocarboxylase	Subcutaneously	10th until the 25th day 15th until the 34th day 25th until the 42nd day	42
2	Controls Pretreated Pretreated	10 10 10	120–160	♂ and ♀ (random)	5	Sodium choride 9°/₀₀ Thiamine Cocarboxylase	Subcutaneously	15	40
	Controls Pretreated	20 10	90–100	♂ and ♀ 1 : 1	7·5	Sodium chloride 9°/₀₀ Cocarboxylase	Intraperitoneally	15	30

Our experiments confirm, as shown in Fig. 1, a difference between the sexes in susceptibility to the analgesic effect of morphine, female rats being less sensitive at the same body-weight—and consequently for the same total dose—than males.

Di Mattei's hypothesis[8] on the relations between the functions of certain vitamins and the pharmacological effects of some drugs suggests that morphine may affect in some way biological processes in which thiamine is involved.

Effect of Hypothermia on Death by Starvation

It is known that during the winter months some animals adjust themselves to unfavourable living conditions, particularly food shortage, by hibernation. This leads to a considerable lowering of the total metabolism and a drop in body temperature which enable the animals to survive the winter with a minimum consumption of nutrient.

Recently some very interesting substances have been prepared, for example, chlorpromazine, which produce an effect in some respects resembling hibernation. Hence the term 'artificial hibernation'. Chlorpromazine has been used with good results in psychiatry, surgery, pædiatrics and clinical states with a general hyper-reactivity of the patients.

We attempted to solve the problem, whether the effect of this substance can in some manner protect the animal from death from starvation, as this is, no doubt, the main purpose of hibernation in Nature.

The experiments were carried out on rats. We used 10 rats which had been fed on a standard diet (Larsen). They were then deprived of food while they had free access to water. Half the animals received chlorpromazine (Largactil Specia), 5 mgm./kgm. body-weight daily. The second group was used as control. Chlorpromazine, which lowered the body temperature of the experimental group by 3° C., caused a general apathy with a lowering of voluntary movements, but did not exert any influence on the time of survival (control group $6{\cdot}0 \pm 1{\cdot}4$, experimental group $6{\cdot}5 \pm 1{\cdot}73$ days; $P = 0{\cdot}7$) or on the loss of weight. The weight curves were the same in both groups. Nor was the excretion of nitrogenous substances much affected (control group 120 ± 27, experimental group 100 ± 12 mgm. nitrogen/24 hr./100 gm. weight; $P = 0{\cdot}2$) and ketone bodies (expressed as acetone) in the urine (control group $0{\cdot}18 \pm 0{\cdot}05$, experimental group $0{\cdot}19 \pm 0{\cdot}07$ mgm. ketone bodies/24 hr./100 gm. weight; $P = 0{\cdot}8$).

Apparently the drop of body-temperature under the influence of chlorpromazine was too small to protect the animals from death by starvation. We did not want to use larger doses of chlorpromazine for fear of pharmacological side-effects. Therefore in subsequent experiments we chose young rats (10 days old) because, as is well known from the literature[1-4], their body-temperature can easily be lowered to the environmental temperature. We used suckling rats from the same litter of which half (5 animals) were kept at an optimal temperature of 30° C., the second group at 20° C. Both groups of animals were taken from their mothers at the same time. The body-temperature of the animals kept at 20° C. dropped considerably within 15 min. and the rate of respiration decreased by as much as 40 per cent. In spite of this the group which survived in the colder environment was not protected against death by starvation. The time of survival at a temperature of 30° C. was $98 \pm 13{\cdot}6$ hr., at 20° C. $85 \pm 9{\cdot}9$ hr. ($P = 0{\cdot}2$). The total weight-loss as compared with the control group was, however, less than half (12·5 per cent loss of body-weight in animals kept at 20° C.; 34·3 per cent in animals kept at 30° C.; $P < 0{\cdot}01$). It is interesting that the relative composition of the carcase was, in both groups, practically the same. The animals kept at 30° C. had at the end of the starvation period a carcase composition of 80 per cent water, 20 per cent dry matter, 2·4 per cent nitrogen; the animals kept at 20° C. 82 per cent water, 18 per cent dry matter, 2·1 per cent nitrogen. During starvation, however, the control group kept at 30° C. lost 2·1 gm. more water (that is, 175 per cent more).

The animals kept at a temperature of 20° C. were pale, apathetic, with voluntary movements reduced, and a slow rate of respiration. The opposite was true of animals starving at 30° C.; they also had very strong sucking reflexes. It is interesting that as compared with the first group we noted a marked growth of fur in these animals during the starvation period.

The most probable explanation of our findings is that the hypothermia caused by chlorpromazine bears no relation to the reduction of the total energy metabolism. This is in agreement with the work of Ankermann and Jung[5], who showed that oxygen consumption in such animals is not reduced but actually has a tendency to rise. Chlorpromazine could cause a lowering of oxygen consumption and a reduction in metabolic rate if at the same time the body was cooled physically, thus lowering the temperature twice as much as in our experiments.

However, even experiments on young rats, where the reduction of body-temperature was as much as 10° C., did not protect the animals from death by starvation. This fact (independently confirmed at another laboratory: Faltová, E., and Konečná, V., personal communication) is very interesting from the point of view of the mechanism of death by starvation, since hypothermia protects animals, particularly young animals, from short-term stresses, such as anoxia, pain and poisons.

From our experiments, and those of other workers using 'artificial hibernation', it appears that the term 'hibernation' is not suitable.

Supplement to NATURE

No. 4614 APRIL 5, 1958 Vol. 181

THE INDIVIDUAL: UNIQUE BUT IMPERFECT

The Uniqueness of the Individual
By Professor P. B. Medawar. Pp. 191. (London: Methuen and Co., Ltd., 1957.) 18*s*. net.

ARTICLES and lectures published by Prof. Medawar over the past twelve years are here collected together and presided over by an essay on the wider implications of skin grafting specially written for the volume. That Prof. Medawar should exhibit an easy command over his material is to be expected; his equal command over the English language will give great pleasure to his readers, whose close attention he constantly rewards by a turn of phrase or a felicity of expression which enlightens as it entertains.

The eight essays range widely, but Prof. Medawar threads them together upon the topical theme of evolution. To this end he devotes his introduction to a defence of natural selection, which prepares the way for the first two essays. These start by formulating the evasive phenomena collectively recognized as 'growing old'; and then develop Medawar's idea that ageing is a consequence of the declining impact of natural selection upon those members of a population who have lived longest and who, owing to the mere hazards of time, contribute least to succeeding generations. That adaptation may proceed faster during the earlier phases of an animal's life-history than later on has important consequences for the comparative zoologist as well as for the actuary.

It is perhaps particularly in "A Commentary on Lamarckism" that Prof. Medawar's interest and skill in the careful definition of terms and the orderly unfolding of an argument are made apparent. Lamarckism takes a 'weak' and a 'strong' form: the weak form asserts that some types of inheritance could be interpreted in a Lamarckian fashion; the strong form asserts that these are correctly so interpreted—an assertion which Medawar finds unproved among the Metazoa and meaningless among the microbes.

Helmholtz's somewhat insensitive strictures upon the human eye were provoked by the perfectionist school of evolution, which may not be vocal to-day. But adaptation is still too often regarded as a condition rather than as a process, an arrival rather than an optimistic journey, and it is against this error that the essay on "The Imperfections of Man" is directed. As a newly evolved organism, man may perhaps be unusually imperfect, but this is hard to assess since he has kicked over the scales, shaping rather than being shaped by the environment, doctoring his ailments and supplementing genetic inheritance by tradition. This is the subject of a short essay on "Tradition: The Evidence of Biology", in which the reader is spared the too obvious and humiliating undertones of a theme which earlier generations of Darwinists would have developed with robust confidence.

"The Uniqueness of the Individual"—the title of the last and longest of these essays—lies at the heart of evolution theory. It is not, however, with the evolutionary aspects of uniqueness that Prof. Medawar is here primarily concerned, but with a new manifestation of uniqueness and the light which this throws on the organization of the individual. The preliminary facts are provided by modern surgery: skin can be transplanted from one part of an individual to another, but not from one individual to another. But there are significant exceptions to this rule: transference is possible between identical twins, members of very pure strains, embryos, or individuals whose blood-streams have been naturally or artificially confluent during embryonic life. Prof. Medawar gives an account of the reasoning and the series of critical experiments by which he and his colleagues, among others, have explored these phenomena.

There are two questions. First, what is the unique substance or group of substances apparently produced by all the tissues of an individual? Secondly when a tissue is transplanted into another member of the same species, what is the mechanism activated by this substance causing the host to treat the graft as a foreign body and destroy it? To these two questions it is to be expected that Prof. Medawar, as a zoologist, should add and discuss the answer to a third: What are the normal functions of these processes which have been almost accidentally brought to light through surgical practice and experiment? He suggests, only to reject, the idea that the tissue exudate is a sort of queen-substance which regulates the growth of the body. But is not the alternative suggestion—that, having passed from the nucleus to perform its function in the cytoplasm, it emerges from the cell as a mere excretion—too great an anticlimax? Excretion is a favourite disguise for elusive physiological processes. Many of these investigations have been reported in specialized medical journals, but they are of great consequence for biology in its widest sense, and biologists of many sorts will be most indebted to Prof. Medawar for publishing this masterly survey of a challenging field of research.

D. A. Parry

THE FACE-CULT

The Eye Goddess
By Dr. O. G. S. Crawford. Pp. 168+48 plates. (London: Phoenix House, Ltd., 1957.) 50*s*. net.

THOSE acquainted with the services which Dr. O. G. S. Crawford rendered to prehistoric archæology will read this interesting, speculative book with mingled feelings of gratitude and regret, since its publication was followed immediately by the author's lamented death (*Nature*, January 18, p. 156). If his chief contribution to the science has been in the domain of air photography and as the founder and editor of *Antiquity*, in this volume (written, incidentally, in the first instance for readers of *Antiquity*) he has shown remarkable powers of detection in the elucidation of obscure symbols on rock-carvings, cult-objects, megalithic monuments and other tombs and temples. These enigmatic figures have long been a matter of discussion and speculation, and in recent years it has become increasingly clear that they were very intimately connected with the cult of the goddess in its various forms and phases.

The axes and daggers which Mr. R. J. C. Atkinson found carved on the sarsens of Stonehenge in 1953 started Dr. Crawford on his quest and eventually led him to a temple at Brak in the Khabur valley in eastern Syria, belonging to the Jemdet Nasr period about 3000 B.C. In this sanctuary, dedicated to the Mesopotamian goddess Inanna-Ishtar, Prof. Mallowan discovered in 1937–38 a quantity of female figurines with very prominent eyes, sometimes associated with similar male figures, representing in all probability cult-images of the mother-goddess and her consort son. Statuettes of this nature, so prevalent from the eastern Mediterranean and the Fertile Crescent to the Indus valley, suggest the wide-spread distribution of a fertility ritual in the ancient Near East connected with the renewal of vegetation at the annual festival in the spring.

On this hypothesis, for which there is reasonably strong presumptive evidence, Dr. Crawford proceeds to trace the diffusion of the "Face-cult" westwards in successive waves overland through, or (as he thinks more likely) by sea around, Anatolia to the Troad, the Aegean, Crete and Greece, and thence to the Danube basin; along the Mediterranean to southern Italy, Sicily, Malta and Spain, with possible extensions to north Africa and the Canary Islands. Northwards, following the Atlantic littoral, it made its way along the coastal megalithic route to Brittany, Ireland, Britain and north-west Europe. Thus, at Los Millares in Almeria, where contacts with the Aegean, Crete, Anatolia and the eastern Mediterranean have been recognized for some time, 'owl-eyes' were painted on cist plaques, bovine phalanges, and stone and ivory cylinders found in megalithic tombs. In the northward extension of the cult the links become increasingly less apparent and problematical; nevertheless, Dr. Crawford has been able to make a fairly convincing case for an unbroken chain connecting its probable appearance in Brittany and Ireland in the second millennium B.C. with that in Anatolia, and ultimately, in the previous millennium, at Brak in Syria. Its arrival in northern Britain, very likely from Ireland with the passage graves, raises a number of problems regarding dating and technique that await final solution. This also applies to the Danish 'owl-faced pots' and their possible connexions with similar sherds from Los Millares, and the other indications of Danish–Iberian relations.

If there are some weak and missing links in the evidence at present available, this provocative volume, with its excellent photographs, drawings and maps, focuses attention on a complex of widely dispersed cult-symbols which hitherto have not received the serious consideration their importance and significance merit. It is indeed regrettable that the author could not complete the inquiry he had begun with such ingenuity and promising results.

E. O. JAMES

DARWIN AND THE HISTORY OF SCIENCE

The Darwin Reader

Edited by Prof. Marston Bates and Dr. Philip S. Humphrey. Pp. ix+481. (London: Macmillan and Co., Ltd., 1957.) 30*s*. net.

WE are here given a reprint of Darwin's "Autobiography" and extracts from several of his books. Some of the extracts are long—more than a third of "The Origin of Species" is included, and about one-sixth of "The Descent of Man". There are also shorter extracts from "The Expression of the Emotions", "Climbing Plants", "Insectivorous Plants" and "The Formation of Vegetable Mould by Earthworms". It is a pity that these last extracts could not have been longer, for Darwin's minor works are some of the most fascinating books in zoological literature, giving as they do a very clear insight into his methods of work as an investigator.

In their introduction the editors state that their object was to provide a book for a course aimed at giving students who will not be scientists, and who will presumably not have much general knowledge of biology, some appreciation of scientific thought. When they read Irvine's biographies of Darwin and Huxley in "Apes, Angels and Victorians", it seemed to them that there was a book that could be used "to build up an illuminating case-history in the development of science", but that if students were to read about Darwin they should also read some of his works. They could scarcely be asked to give the time needed for reading the whole books.

The compilation has been well done, and the book gives a sound view of Darwin's broad outlook as a naturalist and the fairness of his argumentation. But it is less clear that the book is suited to the object for which it was designed. In reading Darwin's work, anyone acquainted with modern biology continually meets passages which would certainly be written differently to-day. At several points Darwin's views have definitely been discarded, as, for example, his belief that the species is nothing more than a stage in the process of differentiation, his attribution of sexual selection to æsthetic appreciation by the opposite sex, and, for most modern biologists, his frequent recourse to Lamarckian inheritance as a real, if not a primary, cause of evolution. It is to be expected that not all his beliefs should be accepted after a lapse of a century, and it is the best test of the soundness of his work that it has stood the test of time with so little modification. But if a student who has not a good background of modern biology reads Darwin, and him alone, he will certainly get an out-of-date view of evolution and its theory.

The book might well be useful in a course on the history of science at a later stage of biological education, though in such a course the books themselves should perhaps be read; no one better than Darwin can easily be found as an exemplar of scientific argument. For the purpose for which the book was designed it would seem that some more recent work would be more appropriate. It is true that a few recent books on evolution are cited in an appendix as suggestions for further reading, but it seems that the student should know the modern theory *before* he takes up the reading of Darwin.

Whatever doubts one may have concerning the use to which the book is to be put, any work that may encourage biologists to take an interest in evolution and the history of its theory is welcome, and this book should certainly do that. It is especially valuable that the "Autobiography" should be reprinted; this has not been done, to my knowledge, since Darwin's "Life and Letters" were published by his son in 1887. G. S. CARTER

THE MECHANISM OF INSECT FLIGHT

Insect Flight

By Dr. J. W. S. Pringle. (Cambridge Monographs in Experimental Biology, No. 9.) Pp. viii+133. (Cambridge: At the University Press, 1957.) 15*s.* net.

THE problem of how insects fly has interested biologists for a very long time. This interest has been intensively revived, partly as the result of the development of new techniques, since the War. Half the references on which "Insect Flight" is based are from the past ten years, showing new productivity which would be sufficient reason in itself for a monograph. But the immediate reasons for its appearance are twofold. One is the realization (by Boettiger and Pringle, independently) that in insect flight muscle, particularly that of the higher orders of insects, there are peculiar physiological mechanisms of considerable interest. The interpretation of these may throw new light on problems of the functioning of muscle tissue in general. The other is the recent publication of several papers which describe a very thorough investigation of the flight of locusts made by T. Weis-Fogh, a brilliant pupil of the late August Krogh. This work made the minimum of assumptions, utilized exact methods and rigorous analysis and thereby greatly illuminated the whole problem. These matters are dealt with in the monograph. At every stage in the presentation new lines of development are made apparent. In particular, the elucidation of the special physiological problems of the flight muscles offers a rewarding challenge, and the aerodynamic problems which have been overcome by extremely small flying insects require clarification.

The monograph illustrates well the newer approach to problems of experimental biology, in which the artificial barriers between collateral disciplines are broken down in the interest of solving a single functional problem. The anatomy, fine-structure, cytology, biochemistry, sensory and motor physiology and flight dynamics of the relevant parts are all given careful treatment. Critics of this approach will have to look hard for traces of superficiality. It is noteworthy in this connexion that most of the recent advances reported have come from zoologists who, like Weis-Fogh, have mastered other disciplines with no other end in view than bringing their techniques and principles to bear on the insect problem. Insect flight has in the past attracted a lot of attention of the arm-chair variety, with the result that it suffers from a number of unwarranted simplifications. Now it has advanced far beyond the string-and-sealing-wax stage and is being placed on a firm foundation of observation and theory.

The text is extremely well illustrated with 52 text-figures including several original drawings. All pay tribute to Dr. Pringle's superb draughtsmanship and unique sense of emphasis. The book suffers from only one fault—that of being difficult to read; but this only reflects the complexity of the mechanisms of insect flight and the inevitable consequences of the distillation of information.

It is a pity that the important work of Rodendorf (1951) on dipteran flight was not covered. Also the observations of Larssen on the thoracic muscles of gyrinid beetles, some of which fly although completely lacking dorsal longitudinal muscles. Pringle notes that the dorsal longitudinal muscles of some beetles are reduced in size. Their function is taken over by the basalar and subalar muscles. (I am indebted to Mr. R. A. Crowson for directing my attention to these papers.)

"Insect Flight" is a book in which many physiologists, biochemists and biophysicists as well as zoologists should find much to interest them. It has the advantage shared with other books in the series of being at a price which one can afford and of a length which permits reading from cover to cover.

GRAHAM HOYLE

FISH PHYSIOLOGY

The Physiology of Fishes

Edited by Margaret E. Brown. Vol. 1: Metabolism. Pp. xiii+447. 12 dollars. Vol. 2: Behavior. Pp. xi+526. 14 dollars. (New York: Academic Press, Inc., 1957.)

The Physiology of the Pituitary Gland of Fishes

By Grace E. Pickford and James W. Atz. Pp. xxiii+613. (New York: New York Zoological Society, 1957.) 6 dollars.

DR. MARGARET BROWN does not tell us how she came to have the idea of asking a number of authors to write upon different aspects of the physiology of fishes. It was a very good idea, and the result has been two volumes that will be of value and delight to many general zoologists as well as to those interested especially in fishes and fisheries research, to whom she says they are specially directed. Although there are no close links between the various sections, there is evidence that Dr. Brown has unobtrusively played a considerable part in editing the whole. In particular, she has herself set for each author the extent of his contribution—an excellent plan, which has ensured special emphasis on fields often neglected or of special interest because of recent work. Dr. Brown's own article on "Experimental Studies on Growth" is a good example. She has succeeded in collecting many fascinating facts about the determination of the age and growth of fishes and relating these to general biological problems.

Inevitably, any book that deals with the physiology of an arbitrarily chosen group of vertebrates will seem in some respects disjointed. One regrets particularly that neither amphioxus nor ascidians have been considered to be 'fishes'. Without them the discussions of the evolution of, for example, digestion and the endocrines inevitably lose some of their interest—though both remain fascinating enough.

The depth of the treatment and extent of literature quoted vary somewhat. There are more than 125 references on the swim bladder, but only eight on colour changes. Generally speaking, the work will serve to give an introduction to the special features of the physiology of the various organ systems of fishes, and in some cases, but not all, will provide a critical discussion of the current problems.

The monograph by Drs. Pickford and Atz on the pituitary of fishes goes much deeper. Every aspect of the subject is treated in the greatest detail, and the result would be fascinating were it not for the severe difficulty of reading imposed by the hideous type, with lines much too long and unaligned. The effect of this extensive review is to emphasize that a very large body of detailed fact is available and yet is little used by biologists. Co-ordination of ideas only becomes possible when a full and scholarly treatment such as the present one becomes available.

An interesting feature is the discussion of the use of injection of pituitary extracts in pisciculture in Brazil and the U.S.S.R. The authors have gone to great trouble to obtain translations from the original papers published in those countries. They are able to present a full survey of the techniques, and the results claimed for them. It is especially interesting to have an account of the sequence of enthusiasm for the method by the schools of Skadovskii and Gerbils'kii and the criticisms by Derzhavin. The work has involved very thorough study of the breeding habits of the various races of sturgeon and other fishes and comparison of the results of natural and artificial spawning methods. That the former should be the more efficient is not surprising, but the latter is becoming increasingly necessary as the sturgeons are cut off from their up-stream spawning grounds by dams.

The book is dedicated to Prof. Petrunkevitch on his eightieth birthday, and he has himself performed much of the translation from the Russian.

These two works together emphasize that comparative physiology is growing up into an extensive discipline contributing greatly both to theoretical and practical biology. J. Z. YOUNG

HISTOLOGY

A Student's Histology

By H. S. D. Garven. Pp. xii+650. (Edinburgh and London: E. and S. Livingstone, Ltd., 1957.) 55*s*. net.

OF the various text-books of histology of the traditional type, designed to meet the needs of the medical student, this is one of the best I have seen. It is an excellent work which despite minor blemishes deserves great praise. Dr. Garven has succeeded admirably in steering a course between what he terms "the Scylla of elaborate detail . . . and the Charybdis of over-simplification". The essential facts are presented clearly and concisely yet the student is always encouraged to keep an open mind and be prepared, when necessary, to consider more than one point of view. The diagrams are in general simple but effective, clearly emphasizing the points to which attention is being directed—for example, the scheme of the splenic circulation on p. 251, or the figure of the renal corpuscle on p. 438. The only doubts which assail one in reviewing such a book concern the extent to which the teaching of histology should incorporate some of the revolutionary changes which are now taking place.

It was in 1850 that Kölliker produced one of the earliest classical texts in histology, and it is interesting to note that this pioneer in his subject, who was professor of anatomy and physiology at Würzburg, gave his book the title of "Mikroskopische Anatomie". The great anatomist Jacob Henle had already, in 1841, extended the scope of anatomy from macroscopic down to molecular detail. In the introduction to a shorter "Handbuch der Gewebelehre", published in 1852, Kölliker wrote: "If it be possible that the molecules which constitute cell-membranes, muscular fibrils, axile fibres of nerves, and so forth, should be discovered, and the laws of their apposition, and of the alterations which they undergo in the course of the origin, the growth, and the activity of the present so-called elementary parts, should be made out, then a new era will commence for histology. . . ."

In the light of the vast body of new facts which in our own day are so rapidly accumulating through the use of the electron microscope and other agencies, Kölliker's prophecy of 105 years ago is well on the way to fulfilment. The new era in histology which he foretold has indeed commenced. From now on text-books of histology must incorporate to an increasing extent the newer concepts, which will bring histology ever closer to the molecular level, and demonstrate with yet greater precision the integration of structure and function, as the newly explored territory of the cell is mapped out afresh. J. M. YOFFEY

NORTH AND CENTRAL EUROPEAN FLORA

Flora von Nord- und Mitteleuropa

Von Friedrich Hermann. Pp. xii+1154. (Stuttgart: Gustav Fischer Verlag, 1956.) 98 D.M.

THIS is a remarkable book. It is the work of an amateur botanist living in a small town about 85 miles south-west of Berlin and therefore without ready access to the vast amount of literature concerning European plants which has accumulated during the past two centuries. Nevertheless, it contains a great deal of information, both descriptive and distributional, in a single volume of convenient size but unreasonable price. The brief preface gives all too little information about the area covered, the sources used (there is no bibliography), and the general plan and purpose of the book. One is left longing to know more, particularly of the author's obviously extensive journeys and of his views on species and subspecies.

So far as can be discovered from the preface and from the species included in and excluded from the body of the work, the area covered may be outlined roughly as follows: Iceland, Spitsbergen, Fennoscandia, Poland, Carpathians, Bulgaria, Alps (south to the Alpes Maritimes), the line of the Rhône and Seine and the British Isles. The author has, he says, no personal knowledge of the western Alps, the British Isles, Iceland and Spitsbergen, but appears otherwise to have sampled the area with such thoroughness that he claims to have seen the majority of the species growing wild and to have cultivated many of them in his garden.

The descriptive part of the flora occupies rather more than 1,000 pages and deals with approximately 4,500 species, which is a little more than a quarter of the estimated total number of species in Europe. The exclusion of the Iberian peninsula, most of the Balkan peninsula, a considerable part of east Europe and of all the Mediterranean plants, except for the few which ascend sheltered valleys in the southern Alps, accounts for the remaining three-quarters of the European flora.

The well-known Engler and Prantl system of classification is followed, perhaps a slight disadvantage to some British users of the book. The descriptive information is contained in extended keys which are clearly set out and easy to use, though in places rather fuller descriptions would have been helpful. These keys often contain information derived from personal observations, which greatly enhance the value of the work. Flower colours are described in general terms and then often made more precise by reference to Ostwald's colour scale: a useful innovation.

Not infrequently two or more taxa are keyed out together and then indicated in such a way as to leave one in complete doubt about whether the author regards them as species or subspecies or even varieties. For example, in the key to *Cytisus* (p. 592) he has:

"4. . . . Hülse ganz kahl (*leiocarpus* Kerner 1863) bis angedrücht seidenhaarig. . . . *ratisbonensis* Schäffer 1760.

4* . . . a) Krone weiss bis blassgelb, Kelch zottig, bis 12 mm. lang. *albus* Hacquet 1790. a* Krone sattgelb. *austriacus* L. 1763. . . . *austriacus* L. 1763.

One might guess from this that *leiocarpus* is to be regarded as a variety of *C. ratisbonensis* and that *C. austriacus* has two subspecies, but when one looks at the distributions one finds all three taxa are given binomials, as though they were species.

Other, though less important, peculiarities are the fairly abundant invention of new sectional names (indicated by asterisks), without a word of definition, and certain liberties with nomenclature. Herr Hermann believes in consistency more than in the international code. He says, "Ich schreibe daher stets chloa nicht bald chloa, bald chloë", etc., and prefers *Heleocharis* to *Eleocharis*.

T. G. TUTIN

CHROMOSOME SCIENCE

Cytology and Genetics

By Prof. Carl P. Swanson. Pp. x+596. (Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1957.) 13.35 dollars.

THIS is an ambitious book. It sets out to cover every aspect of nuclear cytology, the function and structure of the chromosomes, their movements and their crossing-over, their variation and their evolution, their chemistry and their organization into genes; and, very properly, it seeks throughout to integrate the information from cytological examination with the results of the breeding experiment. Twenty-five years ago this was already a big task to essay. To-day it is tremendous and the author is to be congratulated not only on his courage in tackling it, but also on the success he has achieved. In surveying, and be it noted surveying at the research level, so large a field, Dr. Swanson inevitably finds himself dealing with much that is away from his own direct interests. Equally inevitably, this is reflected in the quality of the treatment. There is a confidence, for example, in the handling of induced aberrations of the chromosomes, which is lacking from the treatment of nuclear behaviour in differentiation. Again, a topic is sometimes taken up more than once in different parts of the book, with conclusions that are not always fully co-ordinated; but this is scarcely to be avoided in so extensive a survey.

It is a measure of the book's achievement that "Cytology and Cytogenetics" invites comparison with Darlington's "Recent Advances in Cytology", first published twenty-five years ago and revised in 1937. In aim and scope the two books are very similar. Much new material has, of course, accrued since the earlier book was written, and the light of observation and experiment can now be thrown on questions which were then only beginning to loom ahead. Yet it is remarkable how often this later development is in some sense foreshadowed in the earlier work, and the two books are clearly talking about basically the same matters in essentially the same language. The real contrast between them lies rather in the author's approach. "Recent Advances in Cytology" sought to assemble the facts of chromosome behaviour and its genetical implications in terms of the comprehensive theoretical structure which Darlington has done so much to give to this science and which has provided the basis for its continuing development. Swanson, on the other hand, is content to ask questions and to give such information as is available about them, without pressing far into what he would doubtless regard as the speculatively theoretical in reaching answers. In consequence, to quote from his preface, "The reader will observe that few definitive answers can be given". Many will, no doubt, applaud this approach as permitting a fairer appraisal by letting the facts speak for themselves. To others it will be less obvious that this advantage can be counted on to follow, for left to themselves facts seldom fall into a complete or tidy pattern. Difficulty in reaching an answer can result from failure to confront the facts squarely with one another and reduce each to its true significance in relation to the rest. As Charles Darwin pointed out, theory supplies a guide to observation, and, even more to the present point, it can also stimulate the re-examination and reassessment of the 'facts' themselves. Obviously, no theory can be pressed in the face of recalcitrant but incontrovertible fact. But are all so-called facts of observation to be taken on their face value? Where everything fits except for some apparently stubborn observation, should the theory promptly be sacrificed? Or should not the observation first be re-examined in respect both of its validity and the significance attached to it? It is a rare observation which does not have some element of interpretation about it, and while to dismiss the observation out of hand simply because it is awkward is to miss the lead to truer understanding, to accept it unquestioningly on its face value is to invite frustration and confusion.

This problem of acceptance is well illustrated by Swanson's treatment of chromosome structure in relation to meiotic pairing. He dismisses a chemical theory of pairing proposed by Delbrück (p. 213) and also Darlington's precocity theory of meiosis (p. 212) on the ground that they are inconsistent with what he variously describes as the cytological fact and the idea that chromosomes are already divided and double at leptotene. The evidence from chromosome morphology suggests that each chromosome or chromatid may, in fact, be multipartite in structure, but what does this mean for chromosome function? We learn (p. 121) that the chromosome behaves to X-rays as though it were single during interphase but double at mitotic prophase. Further, the evidence from deoxyribonucleic acid content (pp. 415–416) indicates that this doubles during interphase prior to mitosis, but that synthesis is not completed until zygonema (zygotene) or pachynema (pachytene) at meiosis. Now all that, for example, the precocity theory requires to provide its elegant account of behaviour at meiosis is the assumption that a division or doubling in the chromosomes, functionally effective in respect of their behaviour in pairing, takes place during interphase before mitosis but is not effected until pachytene at meiosis. The evidence of behaviour in respect of X-rays and deoxyribonucleic acid synthesis agrees with this; yet Swanson rules it out, without proposing any alternative, on the basis of static observations of chromosome morphology. Can such fully coherent evidence of behaviour be ruled out solely on that of structure, however valid the observations of morphology may be? Or should we not rather see the question as that of why a functional unit is structurally multiple and of how the structural entities are tied together into a single functional unit? Indeed, Swanson himself asks virtually this very question when he is considering structure in relation to X-ray effects. Further, he is prepared to accept the functional singleness of the chromatid when he is favouring Belling's hypothesis of how crossing-over comes about (a hypothesis, we may note in passing, with a serious intrinsic weakness in that, without subsidiary postulates, it fails to give an account of that most important feature of crossing-over, the occurrence of interference). It is thus not easy to share his rather surprising confidence that structural complexity puts at least singleness in respect of pairing properties completely out of court. The task is surely one of seeking to reconcile the evidence from behaviour and structure, of interpreting the physiological and the anatomical each in terms of the other, rather than of setting them in opposition as alternatives so that one or other must be abandoned.

The same problem of how function is related to structure is at the root of the lively discussions in progress to-day about the nature and organization of the gene. This has been repeatedly emphasized by Goldschmidt and others, and indeed it emerges, albeit somewhat sideways, from Swanson's account of chromosomes and genes. Yet one still feels that if he had been readier to grasp the theoretical nettle the reader would have emerged with a clearer idea of what is at issue, of where we stand and where we are heading, and with less of a sense of conflict than this chapter manages to convey.

Such comments could be extended to other parts of the book, and one might perhaps wonder whether the inclusion of a little more genetics, as, for example, when discussing the role of chromosome inversions in wild populations, would not have made clearer the significance of the cytological findings. These are, however, all comments on treatment, interpretation and opinion. The value of "Cytology and Cytogenetics" as a factual record is not in dispute. Misprints and misusages are few, and at least one reader quarrelled only occasionally with the author on the grounds of misleading statement or omission. This book will be widely used, and deservedly so, especially by postgraduate students of cytology and genetics; and if at times it provides them with the material for exercising their own judgment in questioning the author's conclusions, that is scarcely to be regarded as a defect. K. MATHER

RECENT RESEARCH ON PHOTOSYNTHESIS

Research in Photosynthesis

Edited by H. Gaffron, A. H. Brown, C. S. French, R. Livingston, E. I. Rabinowitch, B. L. Strehler, and N. E. Tolbert. (Papers and Discussions presented at the Gatlinburg Conference, October 25–29, 1955.) Pp. xiv+524. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 12 dollars.

MANY scientists at present actively engaged in research in photosynthesis met at Gatlinburg, United States, in 1955 to discuss their work and current problems. This book contains summaries of the papers presented, and in addition allows the reader to share some of the animation of the conference by printing much of the discussion which followed them. The editors are to be congratulated on producing a well-prepared, readable book from what must have been a confused transcript.

The book will be of the greatest value to the specialist. Largely due to the brilliant exploitation of carbon tracer in the study of photosynthesis the mechanism of the process can be now stated in broad biochemical terms. The remaining outstanding problem is the mechanism whereby light energy is converted to chemical-bond energy in the form of reducing power. This subject dominated the proceedings of the conference and was dealt with under five headings. First, the photochemistry of chlorophyll *in vitro* was discussed; a consideration of the primary photochemical process *in vivo* followed, largely centred on the analysis of spectral changes induced in photosynthetic cells during illumination and on studies of chemiluminescence of photosynthetic cells. The observed spectral changes could not be interpreted in terms of a change in the photosynthetic pigments alone; the changes in the yellow portion of the spectrum indicated the probable functioning of a cytochrome system. The possible role of cytochromes constituted the third topic and was extensively considered with reference to the photosynthetic bacteria, including the obligate anaerobe *Chromatium*. Another discussion was concerned with the reactions of chloroplasts after isolation from the green plant. The formation and condition of chlorophyll in the living cell were also considered. In addition, a section describing various physiological phenomena was included; much of this concerned the anomalous gas exchange which occurs immediately after the initiation of photosynthesis in the induction phase. It is a great convenience to have all these facets of photosynthetic research assembled in a single book.

Besides the large number of papers describing original work, three of the sections commence with a general review paper, and some others are scattered throughout the book. These are written with the object of introducing one specialist to the work of another, which is nowadays necessary even within a single field of research. Livingston's article on the photochemistry of chlorophyll *in vitro* is a valuable survey for the biologist; so also is Franck's paper on the possible role of an excited triplet state. The discussion following this latter paper emphasizes the difference of opinion between the physical chemist, who is greatly concerned with the difficulty of obtaining sufficient energy from a single quantum for the transfer of an electron to the level of reduction of coenzyme, and that of the biochemist who prefers the simpler view that one electron is transferred per quantum. Kamen's article on the possible role of cytochromes is an excellent example of the biologist stating his view to the physical chemist. Such conferences as that at Gatlinburg fulfil a real need in stimulating discussion between workers from different scientific disciplines.

The general reader will find the book primarily of use as a source book of references. Unfortunately, from his point of view, it was not possible to include much of the work concerning the carbon metabolism of photosynthesis. The conference was intentionally limited to a detailed discussion of a few topics rather than attempting a complete survey.

C. P. Whittingham

NUCLEAR CHEMISTRY

La Chimie Nucléaire et ses Applications

Par M. Haïssinsky. Pp. vi+652. (Paris : Masson et Cie., 1957.) Broché, 5,000 francs ; Cartonné toile, 5,600 francs.

It is fitting that the country in which radioactivity was first discovered should be the first to publish a major text-book which surveys virtually all the sciences and techniques in which radioactivity has come to play a part.

The first chapter, "La chimie nucléaire—ses grandes étapes", is an admirable account of the early work on radioactivity. There is the story of Becquerel's mystification over the strange trick of Nature that gave some uranium compounds both radioactive and strong fluorescent properties, and the way the Curies solved it in discovering the other radioactive elements : "la lucidité et la sûreté avec lesquelles ils ont advancé vers le but qu'ils s'étaient proposé, sur une voie jamais encore tracée". In this chapter there are included interesting pictures showing the blackening of the photographic plate which Becquerel first observed, and facsimiles of pages from the note-books of the Curies and of Rutherford.

Following this beginning, there are five chapters on the physical basis of radioactivity and three chapters on the radioactive elements, including the transuranium elements. The transuranium elements are divided into the 'uranides' (multivalent elements) and the 'curides' (mainly trivalent elements), but I feel this subdivision leads to words that sound badly in an English pronunciation, and it is not a clearly defined subdivision. These chapters lead up to the applications of radioactivity in geology and astrophysics, and there are good accounts of such problems as the determination of the age of the Earth. Following this, there comes a section comprising almost a third of the whole book, devoted to radiation chemistry. Separate chapters are given to the effects of radiation on gases, water and aqueous solutions, organic systems, solids and fluorescent systems. There is also a valuable chapter on the chemical effects associated with nuclear transformations. The last part of the book describes radioactive tracers and their applications and includes chapters on electrochemistry, reaction mechanisms, analysis, biochemistry and industrial processes.

A criticism of the book is that it attempts to make into one subject something that is really dispersed over a great many quite separate subjects. Nuclear chemistry in Britain, and in the United States, is normally regarded as a rather small subject restricted to a study of atomic nuclei and their reactions. Of this there is comparatively little in the book and it is discussed rather briefly. The chapters on radiation chemistry, on the other hand, constitute a major review suitable for a research student who would be interested neither in the nuclear problems, nor in the behaviour of radioactive tracers. The book is a notable attempt to bring order into a confused situation, but in practice, if the book were to be translated into English, it is not clear what type of student in Britain would find it useful.

The references are very full and up to date throughout the whole book, and in this respect the author has done a great service in assembling them. Minor criticisms are that there is no collated information such as a complete table of isotopes, or of cross-sections, and that the author index often lists several different people under one name by being restricted to one initial. There are also numerous typographical errors, particularly in such details as the alignment of subscripts, but errors in the actual text are very few for a book covering such a wide field.

G. N. Walton

PAPER-MAKING

Fundamentals of the Beating Process

The Theory of the Development in Pulps of Paper-making Characteristics by Mechanical Treatment. By H. W. Emerton. Pp. xvi+198 (145 figures). (Kenley : British Paper and Board Industry Research Association, 1957.) 42*s*.

This volume refers to the mechanical treatment undergone by pulp fibres in preparation for paper making, and its author is principal research officer (physics) of the British Paper and Board Industry Research Association. It is addressed primarily to the paper-mill chemist, but it can also be read with much profit by all interested in fibre and cellulose science. A special feature is the numerous light- and electron-micrographs illustrating techniques of which Emerton is a recognized leading exponent.

Part I deals with the chemistry and structure of cellulose fibres. Part II covers the theory of beating (the most important and controversial chapter of the book), factors affecting the beating behaviour of pulp, methods for the determination of the progress of beating, and the effect of beating on the properties of paper. It is concluded that beating to produce strength increases the bonded area between fibres by making them plastic, so that they deform by surface tension during drying. Deformation provides the opportunity for bonding, the extent of which will depend on the degree of dispersion of the cellulose and other polysaccharides of the surface layer.

It will be seen that the general treatment is on a relatively elementary scientific plane, the purely practical mill aspects of the subject being deliberately excluded. There are a full index, and a liberal bibliography for the benefit of scientific readers outside the industry.

Julius Grant

THE THEORY AND PRACTICE OF SHIELD DESIGN

Radiation Shielding

By B. T. Price, C. C. Horton and K. T. Spinney. (International Series of Monographs on Nuclear Energy. Division 10: Reactor Design Physics, Vol. 2.) Pp. ix+350. (London and New York: Pergamon Press, 1957.) 60*s.*; 10 dollars.

TWO books which deal solely with radiation shielding are now available to shield designers. Until the volume by Price, Horton and Spinney appeared, one had to be content with either a miscellaneous number of unrelated reports or the U.S. Atomic Energy Commission's "Shielding Design Manual", which while of great value as a comprehensive collection of data, remained very much a handbook. The first impression one obtains from the present volume is that a real effort has been made to put this untidy subject in order and, furthermore, a praiseworthy and generally successful attempt has been made to apply a fundamental and critical approach throughout. It is, in fact, a textbook on the subject, and although the theoretical interpretation and analyses, particularly those of Chapter 4, may appear tedious and complex to the engineer, they nevertheless form a substantial and reliable base from which to work into the future.

The book contains six chapters, the first of which deals briefly but adequately with the health physics aspects of nuclear radiation. The second analyses the attenuation of gamma rays and high-energy electrons and considers in detail the modes of interaction and sources of radiation. These effects are well understood and amenable to calculation except in so far as gamma build-up factors are concerned, and here the authors discuss the moments method due to Spencer, Fano, Goldstein and Wilkins. This, while applicable to massive bulk shields, which approach the idealized system for which the method was derived, is difficult to apply to the complex laminated shields of small mobile reactors and is likely in such cases to be subject to large errors. Nevertheless, this is a lucid chapter, as is Chapter 3, which presents the basic nuclear physics theory essential to any understanding of the problem of neutron attenuation. The following chapter, and perhaps the most important, deals with neutron attenuation in thick shields, and it is in the theoretical analysis of this aspect that the greatest uncertainties in shield design are to be found. The secret of success in the design of a reactor shield system, in terms of achieving the desired attenuation with minimum weight and cost, lies in the accuracy with which one can predict the neutron energy and spatial distribution in the shield. The authors advocate the use of a semi-empirical method based on age and diffusion theory using a fast group consisting of an integrated flux greater than 1 MeV. described by a simple attenuation process, an intermediate group described by an age kernel integrated over $1/E$ spectrum, and a thermal group described by diffusion theory. They show that good accuracy is obtained by this method for bulk concrete shields, but difficulty will again be experienced in applying it to the complex metal hydrogenous shields of small mobile reactors. One would have welcomed consideration of simple multi-group diffusion theory, which is showing promise as a straightforward and accurate method of predicting neutron distribution in this type of shield. This chapter also includes a section on the effects of ducts and voids in shields and provides a sensible treatment of a problem which has not generally been aired. Chapter 5 offers a well-balanced selection of basic mathematical formulæ encountered in shielding calculations. The engineering factors of shield design, including fabrication techniques, heating and thermal stress effects, and their inter-relationship with the physics considerations dealt with earlier, are discussed in Chapter 6. It is a necessarily compressed chapter but will be found to be of considerable interest. A genuine attempt has been made in the section on concrete to give guidance to design engineers in various practical matters, including the avoidance of cracks and streaming paths. Sections on the cost of shielding materials, induced activation of materials and coolants, on beam traps and shielding windows conclude the chapter.

The subject index is extensive and free of anomalies and each chapter is followed by an exhaustive list of modern references. This is a well-written and worthwhile book on a subject which has for too long been kept in comparative theoretical obscurity.

J. EDWARDS

GRAIN BOUNDARIES IN METALS

Grain Boundaries in Metals

By Dr. D. McLean. (Monographs on the Physics and Chemistry of Materials.) Pp. x+346. (Oxford: Clarendon Press; London: Oxford University Press, 1957.) 50*s.* net.

TECHNICAL metals are polycrystalline, and many of their properties depend on the grain boundaries. That is reason enough to have a book on the subject. But it takes five parameters to define merely the orientational relationships at a grain boundary: it is not very surprising that there is still no general exact theory of their behaviour. There has been progress, though, accelerating in the past decade. Some myths have been eliminated, the more sensible of the earlier ideas have won general acceptance, and a broad understanding has been attained within the compass of admitted approximations. If for nothing else, this book is to be welcomed as a reasoned index to the now very extensive body of literature on the subject. The free energies of grain boundaries and their effect in determining microstructure, the adsorption and diffusion of solutes at grain boundaries on intragranular deformation, grain-boundary migration, grain-boundary sliding and intergranular brittleness are all fully discussed.

The author is an efficient reporter of the work of others. His own contributions are for the most part sensible rather than penetrating. His grain-boundary model for the discussion of grain-boundary adsorption (three atoms thick, a mixture of three classes of atom sites, one-third large, one-third small and one-third normal) is probably worth still further detailed consideration for lack of a better. The author occasionally makes elementary mistakes. His claim on p. 50 to measure the line tension of a triple junction of grain boundaries is based on an obvious misconception of surface-tension phenomena—he should look at any liquid surface meniscus in a sharp corner. The subject of grain-boundary melting in pure substances frequently gives trouble, and here is no exception. Somehow the author's thermodynamics teaches him (p. 100) that if λ_B and λ_{SL} are the free energies per unit area of grain boundary and of solid–liquid interface, respectively, then at some temperature below the melting point, at which ΔF is the free energy of melting per unit volume, a thickness $t = (\lambda_B - 2\lambda_{SL})/\Delta F$ should melt at the boundary, and he is left wondering why there is so nice a balance as there appears to be between λ_B and $2\lambda_{SL}$. He could have reflected that it is the property of a free energy to tend to a minimum, rather than to the value you first thought of, and $t\Delta F + 2\lambda_{SL}$ is minimum when t is zero. Nevertheless, by carefully reviewing all the experimental evidence he reaches the sane conclusion that grain-boundary melting has probably only been observed where there are impurities. A sharper-minded theoretician might have skipped the experimental evidence, to our loss.

F. C. Frank

LATTICE DEFECTS IN IRRADIATED SOLIDS

Radiation Effects in Solids

By G. J. Dienes and G. H. Vineyard. (Interscience Monographs in Physics and Astronomy, Vol. 2.) Pp. viii + 226. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 6.50 dollars.

THE production of various types of lattice defects in solids by the action of high-energy radiation, and the changes of physical properties brought about by these defects, have become in recent years one of the most actively studied branches of solid-state physics. This activity is a double response to the development of nuclear technology; on one hand, the experimentalist is now provided with sources of high-energy radiation far beyond those available fifteen years ago, and on the other he is expected to provide materials for nuclear reactors that are able to withstand intense radiations for long periods of time. The subject of 'radiation damage' is thus quite unique in the way that it links solid-state physics directly to both nuclear physics and the technology of materials.

Although several review articles have been published, this is, to the best of my knowledge, the first book that has appeared on the subject, and the authors are to be congratulated on a very successful outcome to their efforts. They have concentrated deliberately on effects of 'knock-on collisions', in which atoms are displaced from their lattice sites by particles such as fast neutrons, protons, electrons, and fission fragments, rather than on ionization effects. This is reasonable because these collisions are particularly important in nuclear reactors and because they can be exploited to study atomic binding forces in the solid state.

The book brings out clearly the tantalizing stage that the subject has now reached. Looked at qualitatively, or semi-quantitatively, the physics of radiation damage is fairly clear. The underlying theory of displacement collisions has been given a good start by Bohr and Seitz, and appears not to contain any major mysteries. Furthermore, the basic perfection of the crystal lattice has enabled us to define fairly sharply the nature of the various atomic defects that are possible, such as vacancies, interstitials, divacancies, and clusters; also, to understand in broad terms the ways in which they can move about and anneal themselves, and their effects on physical properties. The experimental study of annealing kinetics, and of changes in electrical resistivity, lattice constants, stored energy, and other properties, has also shown that this physical picture is certainly broadly correct. On the other hand, as soon as we ask for precise quantitative values, for example, for the numbers of displaced atoms, for the energies of formation and movement of the various defects, and for their effects on physical properties, the subject becomes difficult and progress is slow. Basically the reason is that we have very few techniques as yet for 'seeing' these lattice defects individually, with the result that their experimental study is mainly inferential, from changes of bulk properties, and uncertain. It seems doubtful that the subject will advance far beyond the semi-quantitative stage until new techniques are developed.

All these aspects are discussed clearly by the authors. The practical problems of radiation damage are less fully treated, although embrittlement of steel and radiation growth of uranium are mentioned, and an interesting account is given of the method used to anneal away the stored energy in the graphite moderator of the Brookhaven reactor. Transmutation effects, and the interesting behaviour of inert gases in solids, are not discussed; this is a pity, although it may perhaps be argued that the important aspects of these belong more to the theory of solid solutions than to the theory of lattice defects.

In conclusion, this book can be recommended as a useful introduction to the physics of radiation damage in solids.

A. H. Cottrell

HYDRAULIC SYSTEMS IN AIRCRAFT

Aircraft Hydraulics

Vol. 1: Hydraulic Systems. Edited by H. G. Conway. Pp. ix + 146. 35*s.* net. Vol. 2: Component Design. Edited by H. G. Conway. Pp. ix + 198. 45*s.* net. (London: Chapman and Hall, Ltd., 1957. Published under the authority of the Royal Aeronautical Society.)

THESE two volumes are text-books sponsored by the Royal Aeronautical Society; and several well-known authorities in the aircraft hydraulics field have contributed chapters on their own special subjects. These have been edited by Mr. H. G. Conway, who also contributes himself.

Vol. 1 deals with the more general aspects of the subject. Mr. Bingham, in Chapter 1, discusses the requirements for an aircraft hydraulic fluid and then goes on to deal with the properties of various fluids. Their effect on different sealing materials, storage and inflammability characteristics, etc., are described, and a very useful collection of graphs and tables of the physical properties of these fluids is also provided.

In Chapters 2 and 3 Mr. Collinson deals briefly but effectively with hydraulic theory and fluid flow in orifices and pipes, providing some useful nomograms and charts for determining rates of flow. There are sections on surface tension, viscosity, compressibility and Bernoulli's theorem, to mention only a few. A brief account is included of the gas laws, with which one is obviously concerned when designing accumulators or air bottles.

Next Mr. Parker and Mr. Conway discuss hydraulic systems and circuits. It is obviously impossible to lay down a set of rules for designing a complete system in a text-book; but in Chapters 4 and 5 various aspects, including pumps, piping, jacks and circuits, are considered and sound advice is given on both desirable and undesirable features for a system.

Finally, Mr. Black considers the installation, operation and testing of a hydraulic system in an aircraft. He very wisely emphasizes the importance of good filtration and careful attention by operating personnel to clean working methods and conditions, and in the section on fault-finding he warns the reader never to assume that a component is too simple to go wrong. Mr. Black also discusses the design and use of full-scale rigs for ground-testing complete hydraulic systems, prior to flight-testing in prototype aircraft.

Vol. 2 deals in detail with components for aircraft hydraulic systems. Separate chapters are devoted to seals, pumps, jacks, servo-controls and many other devices. Space limitations preclude a detailed review of each of the subjects treated, but it may suffice to say that they are all discussed and explained thoroughly. The book abounds with sectional drawings and diagrams of components made by both British and foreign firms; the information given is remarkably complete and represents hard-won and up-to-date experience.

These volumes cover the whole field of aircraft hydraulics and yet the individual subjects are treated so thoroughly that a very good working knowledge is obtained. Particular emphasis is placed on the practical aspects throughout, but this is backed by suitable theoretical explanations. These books can be recommended highly and should prove very valuable to students or technicians starting work in this field. They should also be useful to those more experienced specialists who may wish to refresh their memories on the other man's problems.

THEORY OF SOLUTIONS

The Molecular Theory of Solutions

By Prof. I. Prigogine, with the collaboration of A. Bellemans and V. Mathot. (Series in Physics.) Pp. xx+448. (Amsterdam: North-Holland Publishing Company, 1957.) 48 guilders.

IN theoretical physics it is often more useful to circumvent an intractable problem than to solve it; this is nowhere more true than in the statistical theory of solutions. In principle (as can so often be claimed) the thermodynamic properties of any mixture of molecules are determined precisely by the intermolecular potentials, and one should, therefore, be able to calculate the equation of state from a knowledge of intermolecular forces alone. In practice, however, this is a fruitless undertaking except at densities so low that a virial expansion can be performed with accuracy. Our failure to construct an exact theory of the liquid state is a sufficient indication of the hopelessness of attempting an *a priori* theory of liquid solutions. It therefore becomes pertinent to ask: What should be the aim of theories of solutions and how are we to judge their success or utility? Only to ask this question suggests a promising line of attack. The primary aim of solution theories must be to express in terms of the relevant intermolecular potentials the change in free energy which accompanies the mixing of pure fluids with one another. In order to yield useful results the theory of solutions must, therefore, make full use of the experimental properties of the pure components under conditions which resemble as nearly as possible the condition of the solution itself. This philosophy, in recent years, has led to notable advances, and these are fully and carefully described in Prof. I. Prigogine's book.

Of particular interest in solution theory are mixtures of molecules the intermolecular potentials of which are of the Lennard-Jones type, leading to a short-range repulsion and a long-range attraction. Pure species of this sort obey the law of corresponding states, and this law can be generalized to mixtures of Lennard-Jones molecules provided their force fields are isotropic, and do not differ too greatly in strength. The theory of such mixtures, now known as 'conformal solutions', must, however, be extended in order to describe adequately the properties of mixtures in which there are specific interactions or in which the molecules are of very different size. Prof. Prigogine and his colleagues have been largely responsible for this expansion of the theory, and have also accounted successfully for the properties of special classes of mixtures such as associated solutions, mixtures of isotopic species and certain types of polymer solution.

The mathematical methods used in the book are sufficiently elementary to be followed by the ordinary physical chemist, and the book contains many numerical examples which enable the reader to test his understanding of the theory. The physical arguments are clearly and fully expounded and there is much valuable new material which has not yet appeared in the literature. Altogether this is a thoroughly up-to-date and critical book which can be warmly recommended to those wishing to acquaint themselves with the most important recent developments in the theory of non-electrolyte solutions.

H. C. LONGUET-HIGGINS

SOLUTION OF EIGENVALUE PROBLEMS

Variational Methods for Eigenvalue Problems

An Introduction to the Methods of Rayleigh, Ritz, Weinstein, and Aronszajn. By Prof. S. H. Gould. (Mathematical Expositions, No. 10.) Pp. xiv+179. (Toronto: University of Toronto Press; London: Oxford University Press, 1957.) 48*s*. net.

IF H is a linear operator, the values of λ, real or complex, for which the equation $Hx = \lambda x$ has solutions in x satisfying given boundary conditions, are the eigenvalues of the equation.

If the space of the elements x is finite-dimensional, the eigenvalues can be obtained by standard methods; but these methods may become impossibly difficult when this space is infinite-dimensional (for example, Hilbert space), and it is then that the variational method is of great value in many practical cases. This consists in finding the minima of certain expressions associated with the above equation. If now we introduce more stringent prescribed conditions, then the desired minimum will be raised, or at least not lowered, and we obtain upper bounds for the eigenvalues of the original problem; this is the essence of the well-known Rayleigh–Ritz method. If, instead, we weaken the prescribed conditions, the minimum will be lowered, or at least not raised, and we obtain lower bounds for the desired eigenvalues; this is the essence of the Weinstein method. Aronszajn then dealt with the question as to whether these successive approximations actually converge to the desired eigenvalues.

Prof. S. H. Gould's book sets forth in an admirably clear way the details and proofs of the above, together with practical applications to vibrating rods, membranes, and plates.

The ten chapters are on: systems vibrating with a finite number of degrees of freedom; variational principles for finite-dimensional systems; vibration of systems with infinitely many degrees of freedom; reproducing kernels and functional completion; vibrating rods, membranes, and plates; the Weinstein method in its original form; linear operators in a Hilbert space; the Weinstein–Aronszajn method for linear operators in Hilbert space; application of the Weinstein–Aronszajn method in Hilbert space to the differential problem of the vibrating plate; application of the approximate methods to general differential problems.

The general theory is of interest to the pure mathematician, while the applications will interest the applied mathematician and physicist.

The book makes a valuable contribution in setting forth the above ideas and theories in a systematic way, and it is easily readable by any good postgraduate student. R. G. Cooke

RECENT ADVANCES IN APPLIED MATHEMATICS

Modern Mathematics for the Engineer

Edited by Prof. Edwin F. Beckenbach. (University of California Engineering Extension Series.) Pp. xx+514. (London: McGraw-Hill Publishing Company, Ltd., 1956.) 56*s*. 6*d*.

A CARELESS glance at the cover of this book might lead the reader to expect a text-book on engineering mathematics similar, perhaps, to Kármán and Biot's well-known "Mathematical Methods in Engineering". However, the important word in the title is "modern", as the book is actually a collection of mathematical essays describing some of the developments which have taken place in mathematics during the past fifty years. Each essay is by a different author, and the contributors include such distinguished mathematicians as Solomon Lefschetz, Richard Courant and Norbert Wiener.

The subject-matter is divided somewhat arbitrarily into three sections. The first, entitled "Mathematical Models", is largely concerned with the theory of ordinary and partial differential equations, and most of it will be familiar to anyone with a training in mathematical analysis. There is a chapter on non-linear vibrations, an account of the calculus of variations, and chapters on elliptic and hyperbolic partial differential equations. The use of complex variable methods in problems of plane elasticity is dealt with in sixteen pages, and there is also a short survey of exterior ballistics.

The second section covers less familiar ground, as it deals with problems which the editor calls "Probabilistic". It begins with an account of prediction theory, and the subsequent chapters cover the theory of games, operations research, dynamic programming and Monte Carlo methods. In spite of the title, there is no account of ordinary statistical theory. Much of the material in this section is new, at least in the sense that it is not usually found in general textbooks on mathematical analysis.

Although the final section is entitled "Computational Considerations", a considerable part of it might well have been included in Section 1. The chapters on non-linear analysis and relaxation do include some details of computational techniques, but the sections on matrices, conformal mapping, and functional transforms are devoted entirely to analysis. It is worth noting that the chapter on "Methods of Steep Descent" describes techniques for minimizing a function in n-dimensional space, and is not an account of the 'method of steepest descents' used in the evaluation of contour integrals. The final chapter deals very briefly with high-speed computing devices.

To say that this is a book for engineers is misleading, except in the sense that almost any part of mathematics may have some engineering application. There are few references to engineering problems, and indeed one contributor admits to having very little contact with engineering. But whether the reader is an engineer or not, he is certainly expected to be a competent mathematician. Most of the contributors have tried to present concise yet comprehensive surveys of their chosen subjects, and to do this they have necessarily had to assume a good working knowledge of the main branches of mathematical analysis.

Although all the chapters are well and authoritatively written, there is little cohesion between the various sections. The most valuable parts of the book are probably those describing topics such as game theory in which there are at present considerable developments, and where it is difficult for the newcomer to find his way. The lists of references attached to these chapters will be especially useful. It is less easy to justify the inclusion of sections on such well-known subjects as matrices and the calculus of variations, where there is already no shortage of easily available literature. R. K. Livesley

MATHEMATICS IN SECONDARY SCHOOLS

The Teaching of Mathematics

(Issued by the Incorporated Association of Assistant Masters in Secondary Schools.) Pp. ix+231. (Cambridge: At the University Press, 1957.) 15*s*.

THIS volume, the seventh in a series, concerns itself mainly with a general consideration of the purpose of teaching mathematics in secondary schools. The Committee expresses frankly its lack of authority to comment upon the work in secondary modern schools, though it has a good deal to say about the methods of teaching arithmetic in primary schools. Great stress is laid on the needs of the pupil in relation to the substance and not to the structure of the subject, and the old theory of 'transfer of training' is firmly rejected. Nunn's contribution to this change of emphasis receives full consideration, and reference is made to the effect of the Jeffery Report (printed in full in an appendix).

Two detailed chapters develop the work up to the ordinary level of the General Certificate of Education, and the failure of some pupils is regarded as due to unsuitable teaching methods in primary schools. A suggested minimum syllabus for this pre-entry course is given, with a lengthy discussion of the work of the first five years in the grammar school. "Some General Teaching Topics" contains much material for careful consideration by all engaged in teaching mathematics. Far too many men and women are gallantly tackling work which is beyond their own capability as teachers, and this chapter should be of great value to them.

The chapter on the sixth form is less successful than the rest of the book, and it suffers from an attempt to deal with a big topic within the compass of 25 pages. Although expansions and infinite series come into the basic course there is no mention of the vital question of convergence. There is no mention of mass in the basic mechanics course, though one of the main teaching points in school mechanics is surely the distinction between mass and weight. In the section on analytical geometry the correspondence between a locus and an algebraical equation is developed; it could well have been extended to the realization that the curve separates the plane into areas in which the function is either positive or negative; $f(x) > 0$ can be so much more interesting than $f(x) = 0$.

There is a sensible discussion of the mathematical library, with a good list of suitable books, and elementary books in foreign languages are recommended though none is quoted.

The place of practical work in the mathematics course receives serious attention, and a mathematics room with workshop is suggested.

Lastly, a strong plea is made for the inclusion of statistics in the school course. Even if the scope of the work given here is over-ambitious, the conclusion "that statistics, so long as it is taught as a practical subject, can help to make school mathematics more realistic" well expresses the attitude to this relatively new school subject.

Some fifteen misprints have been overlooked in this first edition, but the Association can expect confidently to need a reprinting very soon. The volume as a whole is of the standard that is expected from the Cambridge University Press. W. J. LANGFORD

A POPULAR ACCOUNT OF RADIO-ASTRONOMY

The Changing Universe

The Story of the New Astronomy. By John Pfeiffer. Pp. xi+244+16 plates. (London: Victor Gollancz, Ltd., 1956.) 18s. net.

WE are very familiar to-day with the problem of communications between scientists and the general public, and we have recently seen considerable and successful efforts in daily and monthly journalism to provide intelligent reporting of the more exciting scientific work of the present day. A more difficult problem is set by the popular text-book, which attempts to explain a whole subject to a reader whose only background is an intelligent, but rather vague, interest. An author determined to write such a book must face rigid restrictions—no mathematics, no formulæ, are allowed; all difficult terms such as frequency, wave-length, galaxy, must be explained.

Pfeiffer has written such a book, and in it he manages to cover the whole of radio astronomy up to the middle of 1956. He started with the severe restriction of knowing no radio-astronomy at all, but he had instead the advantages of twenty years experience of scientific journalism, and of two successive tenures of a Guggenheim Fellowship which enabled him to visit and talk at some length with many of the leading radio-astronomers. His account stems directly from his interviews with the men who did the work, and the history of the subject which he provides is the best we are likely to have for some time. The book is accurate in its facts; so accurate and in sufficient detail, that it can seriously be recommended as an introduction to radio-astronomy.

The contrast between the accuracy and interest of subject-matter, and the style of writing, is remarkable. Mr. Pfeiffer is an optimist. He believes it is possible to explain radio-astronomy in all its complexity to anyone able to read, and he consequently addresses himself to a public whose attention requires to be riveted to each page separately by the use of superlative, hyperbole, and simile. It is safe to say that no radio-astronomer could have written such a book, although such a style would, from them, be appropriate to short magazine articles or popular lectures. I find the style too obtrusive for comfort in such a large dose, and I would be surprised to find anyone who needed such a continuous stimulation of interest and who yet was able to read and appreciate the whole of the book. F. G. SMITH

INTO SPACE

Satellites and Space Flight

By Eric Burgess. Pp. vii+159+14 plates. (London: Chapman and Hall, Ltd., 1957.) 21s. net.

THIS book traces the expected future history of space-travel, from the instrumented artificial satellites which are already in being to the manned interplanetary space-ship which, Mr. E. Burgess thinks, may not come for fifty years or more. The first chapter deals with rocket motors, the dynamics of satellite orbits, and the scientific experiments which can profitably be made in unmanned satellites. The next step into space is the unmanned 'probe' missile, sent to investigate the Moon and Mars on our behalf. Mr. Burgess discusses possible circum-lunar orbits, the optimum transfer ellipse from Earth to Mars, and the design and instrumentation of a lunar-probe missile. Man's first sojourn in space will probably be inside a satellite space-station, and once he feels at home in this remote outpost, his next goal will be the Moon. For, despite its unattractive climate—a near-vacuum with extremes of temperature—the Moon will be prized as a base because it occupies a favourable niche in the hill-and-valley system of gravitational potential. Mr. Burgess describes the problems of the lunar base built either above or below ground, and outlines what is known of the Moon's surface. The last chapter, on manned interplanetary travel, includes a discussion of nuclear and ion rockets, and ends with some gentle speculation on interstellar flight.

Mr. Burgess, a seasoned campaigner in the realms of interplanetary space, is a confident guide, and his prophecies may well come true, if taxpayers choose

PHYSICS

to let their money be spent on space-travel. He is familiar with all the literature on the subject, and he gives a useful list of references at the end of each chapter. He steers a wary course half-way between a popular exposition and a text-book. Though he is careful to avoid mathematical symbols, he does not shirk detail: there is plenty of numerical grist, indeed perhaps rather too much, since all weights and distances are expressed in both English and metric units. This practice has something to be said for it, however, in a subject like space-travel, where the applied scientist, a slave to slugs, has to co-operate with his purer, gram-bound colleague.

In the choice of subject-matter there is little need for improvement, but it is a pity that the same cannot be said for the style of writing. Mr. Burgess can find the happy phrase when he tries, but at times he is content to be slipshod and repetitive, and occasionally it is none too clear what he means. Apart from this intermittent failure to communicate, Mr. Burgess is usually a reliable guide to the untrodden paths of space. But he is not infallible, and it has to be said that the book is marred by too many minor mistakes: on p. 97 and elsewhere he repeats the crucial error which misled the interplanetary theorists for so long, namely, their belief that the weight of structure and motor on any missile (or stage of a missile) could not be much less than 20 per cent of the total, though even in 1952 the *Viking* achieved 15 per cent; p. 63 needs thorough revision; Fig. 1.2 is in error; and there are more than thirty other trivial errors or misprints. D. G. KING-HELE

LOGICAL STUDIES AND INDUCTION

Logical Studies

By Prof. Georg Henrik von Wright. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. ix + 195. (London: Routledge and Kegan Paul, Ltd., 1957.) 28*s*. net.

The Logical Problem of Induction

By Prof. Georg Henrik von Wright. Second revised edition. Pp. xii + 249. (Oxford: Basil Blackwell, 1957.) 25*s*. net.

A REVIEW of these two volumes together may serve to show the range and depth of Prof. G. H. von Wright's thinking. His "Logical Studies" comprises a series of eight papers—five of them published previously—and the "Logical Problem of Induction" is essentially his *doktor-arbeit* submitted to the University of Helsinki in 1941. The present book is a second, enlarged edition of the original work published as Vol. 3 of *Acta Philosophica Fennica*.

With regard to the "Studies", three essays are presented dealing with the problem of logical truth. This amounts to an attempt to clarify the statement that logical truth is at root a tautology; or otherwise expressed, that logical truth is a function of form but not of content. It is valuable to have this theme so competently handled. A general lack of understanding about it may well be one reason (no doubt there are others) why scientists are apt to complain that philosophers do little beyond echoing and complicating the less secure tenets of physical theory. Until some crucial issue focuses attention upon it, experimentalists in particular are naturally reluctant to take seriously a discipline which makes rigid demands upon the structure of ratiocination but has nothing to say concerning that which is in fact the subject, the thing-in-itself as Husserl would insist, and its associated correlates.

Underlying this dilemma is the failure to allow enough for the æsthetic content of each problem, whether scientific or logical. Mere applications or developments of existing knowledge are unlikely to prove coercive, since they rarely provide an opportunity for that contemplative factor which lifts the best human efforts above the useful and the pragmatic. It is for this reason that those about to embark upon any postgraduate course of study or research would find it rewarding to read the first chapter in this collection, namely, "Form and Content in Logic".

The next group of contributions is concerned with modality: it should have a wide appeal because of the relationship to probability and the study of norms. But perhaps the most interesting point here is the recognition that there can be—and actually is—a new modal logic which is relative rather than absolute, in the classical sense. The author maintains the Aristotelian origin of this distinction, namely, ὑποθέσεως against ἁπλῶς. Lexicographically, the emphasis of the former is upon 'that which is under', whereas the latter stresses simplicity or singleness. It would have been helpful if Prof. von Wright had enlarged upon this theme a little, because it would have strengthened his assertion that the relative should include the absolute as a limiting case. The concluding study (the concept of 'entailment') bears an epistemic slant, and gives a broad hint of how close we are to the notion of demonstratability.

Turning now to the "Logical Problem of Induction", this largely follows traditional lines in discussing any respectable justification for that which we all take for granted, and upon which so much of everyday life is based. The upshot is that, broadly speaking, induction cannot be rigorously defended, although this result does not necessarily involve such disastrous consequences as are sometimes feared. Prof. von Wright's treatment of this situation is as follows. The basic thesis is presented in the form, "It is impossible to guarantee, with certainty or with probability, that an unknown instance of the property *A* will also exhibit the property *B*, if *A* and *B* are different properties". (We may perhaps compare this with other 'postulates of impotence' such as that relating to electrostatics or with the second law of thermodynamics, or even with the negative existential quantifier $\sim\exists$, "there does not exist . . .".) It appears that, on contrasting a single statement with truth-frequency for a class of statements, it is reasonable to delete "with certainty or with probability". But criteria of the truth of inductive instances cannot be demanded, though this does not preclude the acceptance of 'symptoms' as applied to experience. Embedded in the whole domain of human thought is the temptation to confuse issues of language and of fact. The classification of the former as a lemma to the solution of Hume's problem is the critical task of philosophy, in contrast to the constructive task with its focus upon given conceptual structures. The analysis of inductive propositions can then be undertaken on mathematical principles. Constructive philosophy is not the tool to use for dealing with Hume's scepticism; it has sufficient material upon which to work in its own field, for which Prof. von Wright has provided a sound foothold, as well as a springboard for inductive studies.

F. I. G. RAWLINS

DAIRY RECORDS

Milk and Butterfat Recording

A World Survey. By E. D. Ashton. (Technical Communication No. 3 of the Commonwealth Bureau of Dairy Science and Technology.) Pp. x+197. (Farnham Royal: Commonwealth Agricultural Bureaux, 1956.) 30*s*.

THE only previous publication dealing comprehensively with this subject was that of the International Institute of Agriculture in 1935. Since then considerable progress has been made in methods of milk and butterfat recording and in the use made of such records, and the number of officially recorded cows has increased from 4½ million to the present figure of approximately 8 million.

This survey is a welcome and highly informative contribution to agricultural literature. The history and development of milk recording in some thirty countries is presented in a concise and comprehensible form, as are the financial and administrative problems inherent in the different systems of milk recording operating under the varying conditions which prevail in these countries.

The book appears to fall naturally into two parts: a general survey of the present state of milk and butterfat recording and a series of detailed accounts of the milk-recording movements in specific countries.

Chapters in the first part trace the development of milk recording from the small beginnings of private and breed society records to the start of official milk recording in Denmark in 1895 and on to the present position wherein more than thirty countries have official milk recording schemes and between one-quarter and one-half of the dairy cows in the main dairying areas of the world are officially recorded. Organization of milk recording and methods of financing these movements are discussed very fully as are the practical aspects of milk recording such as identification of cows, methods of sampling, butterfat testing and milk recording personnel. An extremely interesting chapter is devoted to the use of milk recording on and off the farm, in feeding and breeding policies, and another presents the interest of international organizations in milk recording as a means of increasing economic production of milk to help meet the nutritional needs for animal protein in many parts of the world. In the final chapter of Part 1, the author links the future progress of milk and butterfat recording with other services of livestock improvement. An addendum to the first part comprises an excellent review of the literature on methods of milk recording.

The second part of this survey is devoted to milk-recording movements in different countries. The countries covered include the older agricultural countries of Europe, the newer agricultural countries such as Australia, Canada, New Zealand, Southern Rhodesia, the Union of South Africa and the United States of America and tropical and sub-tropical countries such as India, Israel, Jamaica, Japan, Pakistan, Kenya, Tanganyika, Uganda and Nigeria. Concise information is given concerning the national dairy herd, the development of milk recording, its organization and practice in these countries. Each country has its own particular problems and a system of milk recording which proves satisfactory in one is not always the most suitable in another.

Each section contains a summary and a list of references and there are forty-three illustrations. As might be expected in a book of this nature, there are a number of figures and tables. These are clear and well set out and are most informative. In addition, there are a number of useful appendixes.

The author is to be congratulated on assembling such a fascinating account of the world's dairy herds. The publication is of real value to all those seeking information about methods and achievements of milk recording, whether their interests lie in well-developed agricultural countries or in countries where such developments are growing or are yet to come.

HELEN R. CHAPMAN

SUSPENSION BRIDGES

The Theory of Suspension Bridges

By Sir Alfred Pugsley. Pp. vii+136. (London: Edward Arnold (Publishers), Ltd., 1957.) 42*s*. net.

THE several theories of suspension bridges are presented concisely and clearly in this book together with the principles of the study of the vibration of this type of structure.

After an interesting historical introduction to the subject, there are two chapters on theories of the simple suspended cable, including the analysis of stresses and deflexions for various conditions of loading. The well-known approximate theory due to Rankine is the first of the theories of suspension bridges dealt with in the book. Rankine assumed that the cable is parabolic and inextensible, that the deck girders are rigid and that live loading is distributed uniformly to the cable by the girders. This is followed by an account of the elastic theory due initially to Navier and developed more recently by Steinman, which is an improvement upon Rankine's theory only in respect of the allowance for the elasticity of the cable and girder in the determination of the intensity of uniformly distributed loading on the cable. Finally, the more accurate deflexion theory derived by Melan on the basis of the differential equations of the cable and stiffening girder and its approximation—the linearized deflexion theory due to Godard—are considered. The deflexion theory as developed in the United States by Moisseiff and others has proved extremely valuable for predicting the behaviour of modern long-span suspension bridges. In his treatment of the linearized deflexion theory, the author includes the use of trigonometrical series as well as his own contribution, the flexibility-coefficient approach. The use of the former for solving the equations of the general deflexion theory in the manner proposed by Timoshenko and Steuerman is described in a separate chapter.

There is a useful chapter summarizing approximate methods of analysis for preliminary design, which is followed by two chapters on the vibration aspect. The collapse of Moisseiff's Tacoma Narrows bridge in 1940, due to aerodynamically induced vibrations, emphasized the importance of this phenomenon to the designers of long-span suspension bridges. Thus, Chapter 11 deals with the prediction of natural frequencies and modes of vibration in flexure and torsion, while the final chapter gives an abbreviated treatment of the problem of vibration of suspension bridges due to lateral winds, including the use of scale-model tests.

The book is unique among British works on theory of structures, and its conciseness and lucidity are admirable. It is clearly set-out and contains references to original papers and a select bibliography.

T. M. CHARLTON

The Relationships Between Electroencephalographic and Psychological Data in Normal Adults

Dr. P. F. Werre. Pp. vii+152. (Leiden: Universitaire pers Leiden, 1957. Distributed by Messrs. Martinus Nijhoff, Lange Voorhout 9, The Hague.) 15 florins.

BERGER'S discovery of the potential changes in the brain, which he first published in 1929 and which was confirmed by Adrian and Matthews in 1954, led automatically to the foundation of the science of electroencephalography. Its value was realized when Gibbs, Gibbs and Lennox showed that epilepsy could be revealed or confirmed by the electroencephalogram, and this was further enhanced by its use by Jasper and Walter in locating brain lesions. In the Second World War the electroencephalograph was regarded as a valuable instrument in the localization and assessment of brain damage, mostly of traumatic origin. To the neurologist it is now almost as valuable as X-rays to the surgeon. The next step in the use of electroencephalography is obviously to unravel the problems of psychology. A certain amount of work has been done on patients suffering from psychopathic personalities but much remains to be discovered with normal people in such mental states as frustration, anxiety, insecurity, anger and depression. The aim of this thesis is to record some of this work performed by Dr. P. F. Werre in the Neurological Clinic of the Academic Hospital at Leyden.

The book consists of three parts, comprising a survey of the literature, records of experiments and conclusions. In his survey the author considers the literature on electroencephalographic findings in sleep, emotion, anxiety, fatigue and relaxation, the effect of sensory stimulation and mental activity, etc. In the records of his experiments he discusses its relation to the psychology of the subjects. He is cautious in his conclusions but thinks that some definite psychological grouping of people on the basis of the electroencephalogram can be made. This seems to be particularly so in such matters as social insecurity and frustration. All those interested in electroencephalographic work will wish to read this book. Indeed, it is valuable if only for the bibliography, which covers eighteen pages, and for the survey of the literature which occupies sixty-one pages. Although the experiments were conducted on only a small number of subjects the tentative conclusions offered are very suggestive.

CLIFFORD ALLEN

Reason and Chance in Scientific Discovery

By Dr. R. Taton. Translated by A. J. Pomerans. Pp. 171+32 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1957.) 30*s*. net.

IT is gratifying to see an English translation of Taton's dissertation on the art of scientific discovery. This is, of course, by no means the first attempt to analyse the operation of the creative process; but many of the Continental examples of originality selected by the author for analysis are perhaps new to many British readers. Relying largely on case-histories, the accounts of which are well illustrated by diagrams and many excellent plates, Taton discusses such matters as intuition, the automatic and unconscious activity of the human mind, the power of new instruments and the role of chance and accidental observations in the furtherance of human knowledge. It is, indeed, an exciting theme so long as the reader of these post-mortem analyses does not count it all to be an infallible prescription for discovery. Too often the discoverer, in retrospective self-analysis, is apt to conceal the amount of what Katherine Mansfield calls the "terrific hard gardening"—the laborious, conscious and voluntary informing and equipping of the mind which must precede the break-through on the scientific front. As for the great significance of being able to recognize the unexpected, it is relevant to recall the dictum of Pasteur that chance favours the prepared mind. Still, Taton's book is a scholarly contribution to scientific history, and might, for example, be recommended for parallel reading with Brewster Ghiselin's excellent book on the creative process in the world of music and letters.

EDWARD V. APPLETON

The Transformations of Man

By Lewis Mumford. (World Perspectives.) Pp. 192. (London: George Allen and Unwin, Ltd., 1957.) 15*s*. net.

IN this book the author, in seven successive chapters, analyses the transformations of man in a series of stages from his animal or pre-human existence, through what Mumford classifies as archaic man, civilized man, 'axial man', of the 'axial' or universal religions, old world man of the Old World societies, new world man of the New World, to 'post-historic' man of the present time. Pointing out that man's humanity is now threatened by the possibility of barbarism more elemental than was ever encountered in historic times, he postulates the need of a world culture, and that man's principal task to-day is to create a new self, adequate to command the forces that now operate so aimlessly and compulsorily. He believes that humanity still has the technological, as well as the spiritual and personal resources, to create a future which offers scope to human personality, and in his final chapter, "Human Prospects", attempts to indicate something of what is involved in checking the present dissipation of man's potential energy, vitality and creativeness and turning them to this purpose.

To readers of this series that began with "Technics and Civilisation" and ended with "The Conduct of Life" this will be a disappointing book. Neither in scale nor in execution does it match the earlier books. It is more difficult to read, and neither the philosophy nor the argument is expounded with the coherence and cogency that are demanded of an author who assays to cover his field on his own authority essentially unsupported by citation or reference.

Veterinary Toxicology (formerly Lander's "Veterinary Toxicology")

By R. J. Garner. Pp. vii+415. (London: Baillière, Tindall and Cox, Ltd., 1957.) 35*s*. net.

THE radical changes that have occurred in the sources of toxic hazards to animals can be seen in comparing the present volume with the early editions of its forerunner, Lander's "Veterinary Toxicology". In the latter, more than half the book was devoted to poisonous plants, while in addition, the majority of organic poisons described were of plant origin. Now plants form but one of six sections in the book, and it is clear that the domestic animal must face a barrage of synthetic compounds largely comprised of the herbicides used to destroy the plants themselves. Perhaps in future editions it will be necessary to expand the present short but valuable section on radioactive materials. The situation is summarized in the introduction, where common causes of poisoning are tabulated. It is to be regretted that this section of the book is not fuller and indeed that more statistics are not available. This lack of information, which was emphasized by the Zuckerman Report on Toxic Chemicals in Agriculture, necessarily limits the effective direction of policy to reduce the incidence of poisoning.

The author has organized his voluminous material in an admirable way; inorganic substances are dealt with in alphabetical order, but this codical system has been dropped in considering drugs and pesticides. However, this allows the rational grouping of agents with similar modes of action, and hence economy in the text: it is the approach that is familiar in experimental pharmacology. The whole book is well documented with references which will be of value to practitioner and student alike, and indeed the general sections of the book could be read with advantage by students at their preclinical stage.

P. Jewell

Jets, Wakes, and Cavities

By Garrett Birkhoff and E. H. Zarantonello. (Applied Mathematics and Mechanics: a Series of Monographs prepared under the auspices of the Applied Physics Laboratory, Johns Hopkins University, Vol. 2.) Pp. xii+353. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 10 dollars.

While the subject of jets, wakes and cavities is of considerable interest in fluid dynamics and has attracted the attention of many engineers, physicists and mathematicians, accounts of the field as a whole are very rare. Thus, the attempt to collect the available information in one volume is most welcome, and from this aspect alone the book under review with its almost overwhelming number of references is extremely useful. But since the first author, in particular, has himself contributed much original work to this subject, the presentation bears his stamp and draws together and co-ordinates many fragmentary and seemingly unrelated pieces of information. A wide and complex field is covered and interest in the subject is still very much alive. It is in these still vigorously growing branches that the authors' preferences are most apparent and, perhaps, lead to a slightly one-sided presentation. Altogether, the book affords an excellent introduction to a fascinating subject and will profitably be studied by graduate students as well as general readers who are curious about applied mathematics, hydraulics, or aeronautics.

D. Küchemann

Nuclear Reactors for Research

Edited by Clifford K. Beck. (The Geneva Series on the Peaceful Uses of Atomic Energy.) Pp. xii+267. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1957.) 8.50 dollars; 64*s*.

So much information was presented in such a short time at the 1955 Geneva Conference on the Peaceful Uses of Atomic Energy that several publishers recognized the need for producing edited collections of papers on particular topics. The book under review is such a collection. In Part 1 the uses of research reactors are first discussed and illustrated by extensive references. Descriptions of particular types of research reactors are given in subsequent chapters which comprise Part 2.

Most of the material in the book has appeared elsewhere, but Dr. Beck has made deletions and rearranged parts of the original papers so that with his own additions assimilation is easier. Anyone currently considering whether research reactors can be of use in his particular field would do well to study this book as a guide to what can be done.

Part 1 is bound to attract most interest, and unless the reader is directly concerned with choosing a particular type of reactor or for some other reason concerned with comparing details of the different types, Part 2 may prove a rather long catalogue. However, the number of people with such interests is increasing in both industry and the universities, and to them the book should be more easily read than the alternative sources referred to.

F. W. Fenning

Medical Radiation Biology

By Friedrich Ellinger. Pp. xxxiv+945. (Springfield, Ill.: Charles C. Thomas; Oxford: Blackwell Scientific Publications, Ltd., 1957.) 150*s*.

This is a book written by a physician for physicians and as such it should prove a useful textbook for radiotherapists and a valuable reference book for medical men whose contact with radiation problems is more intermittent.

The book is written almost in lecture-note form. It is strictly systematic and exhaustive, with very adequate cross references. This, together with the 5,000 references, makes it a very valuable information source for all workers in radiobiology. It will not, however, rank as a scientific treatise on radiobiology, for the treatment is rather elementary and didactic. The early chapters on the fundamental aspects of radiation and radiation effects are rather unsatisfactory and some would consider them occasionally misleading. For example, the early statement that it is possible to consider all the effects of radiation under a single biological concept as a 'stimulus' would scarcely appeal to the physiologist.

The greater part of the book is concerned with a detailed description of the effects of radiation on the various tissues and organs of the body in health, disease and malignancy. The effect of externally administered X- and γ-radiation is, of course, the main theme, but the effects of ultra-violet and visible light are also fully dealt with. There is also a valuable section on the effects of radiations arising internally from administered isotopes. Health hazards are kept to the fore and discussed at appropriate points throughout the text.

Glossary of Indian Medicinal Plants

By R. N. Chopra, S. L. Nayar, and I. C. Chopra. Pp. xx+330. (New Delhi: Council of Scientific and Industrial Research, 1956.) Rs. 8.

The object of this glossary is to present a concise record of the information regarding the properties and uses of the medicinal plants of India as a guide to those interested in indigenous drugs.

Much of the information is a result of an all-India survey of medicinal and poisonous plants, visits to centres of learning of indigenous medicine and consulting the literature on local herbaria and libraries.

The plants have been arranged in alphabetical order according to their scientific names, so that there will be no difficulty for readers in finding any particular drug. Many of the commonly used synonyms have been inserted as cross-references to their modern scientific names. Abbreviations have been used in order to compress data into a small handy volume and a list of these has been included for ready reference. When a number of plants belonging to the same genus is discussed, the name of the family to which the plants belong is supplied with the scientific name of the genus. Important vernacular names commonly used in different regions of India have been given, and an index of these names has been provided at the end. The diseases for which the particular plant is used are also briefly described.

A special feature, which will not fail to attract attention, is the inclusion of brief accounts of the active principles of plants so far as they have been worked out. An index of chemical constituents is provided. Under the name of each plant, there are abundant references to scientific journals and books.

S. B. Challen

Cloud Study

A Pictorial Guide. By F. H. Ludlam and Dr. R. S. Scorer. Pp. 80. (London: John Murray (Publishers), Ltd., 1957.) 12*s.* 6*d.* net.

THE basis of this book is a selection, preceded and accompanied by explanatory text, of seventy-three photographs with a frontispiece in colour, from the fine collection of the Royal Meteorological Society, the files of its monthly magazine *Weather* and other sources, including the private collections of the authors themselves who have added much to our knowledge of clouds. All the familiar types of cloud are well represented, but possibly the most commanding picture shows the stupendous wall of cumulo-nimbus cloud surrounding the clear 'eye' of a Western Pacific typhoon. From this, one can well believe the statement that a tropical cyclone is an "organized system of cumulo-nimbus clouds". A useful inclusion for purposes of identification is the photograph of the seldom seen but peculiarly beautiful cirriform noctilucent clouds probably consisting of small dust particles instead of water droplets. These form high up in the stratosphere at altitudes of about 80 km. and may be seen in the higher northern latitudes on summer nights between May and August. The authors explain very clearly the fairly well-known physical transformation of large cumulus clouds into showery cumulo-nimbus. Yet one feels there is more to learn about the great cumulus clouds. What is the critical factor which gives them their sharp outlines and rock-like solidity of aspect notably when piled on the horizon like a mighty range of mountains? Ruskin used to expatiate upon this a hundred years ago.

L. C. W. Bonacina

The Physics and Chemistry of Life

(A *Scientific American* Book.) Pp. xi+270. (London: G. Bell and Sons, Ltd., 1957.) 13*s.* 6*d.* net.

THESE eighteen short essays first appeared in the magazine *Scientific American*. The book begins with a discussion of the origin of life and ends with an article on the electrical activity of the brain. Most of the writers are recognized leaders in the field of work which they have chosen to describe. The subjects include photosynthesis, nitrogen fixation, the structure of proteins in general and of insulin in particular, the nature of genes, enzymes, viruses and nucleic acids, the mechanisms of cell division and differentiation, and the properties of muscle and nerve. The standard of 'popularity' varies a good deal from one essay to another. Some of the authors have assumed that their readers will have an elementary knowledge of organic chemistry; others might have been wiser to have made this assumption: for example, it is not easy to give a clear account of the modern view of fatty acid oxidation without using any structural formulæ.

The article by G. Beadle on the genes of moulds and man shows the way in which the study of the bread mould *Neurospora crassa* has helped to explain how genes act. It may perhaps be selected as an example of popular scientific writing at its best.

Taken as a whole, these essays give a broad picture of some of the more exciting topics of present-day biological research. Considering the very reasonable price of the book it would perhaps be ungenerous to complain of the poor standard of production of some of the diagrams.

D. C. Harrison

Tables of the Non-Central *t*-Distribution

Density Function, Cumulative Distribution Function, and Percentage Points. By George J. Resnikoff and Gerald J. Leiberman. (Stanford Studies in Mathematics and Statistics, Vol. 1.) Pp. x+389. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1957.) 100*s.* net.

THE quantity known as 'Student's *t*' is widely used in statistics to test the significance of a mean; it is, in effect, the ratio z/s, where z is a normal variable with zero mean and unit standard deviation and s^2 is an independent variance estimator distributed as χ^2/ν with ν degrees of freedom. The quantity called 'non-central' t is the quantity $(z + \delta)/s$, where δ is some given constant. Its distribution requires tabulation by triple entry, according to t, ν and δ. Originally, it was required for the power function of tests based on 'Student's *t*', but more recently has found application in a number of other fields.

These tables present the frequency, the distribution function and the percentage points of non-central t to four decimal places for $\nu = (1)24(5)49$; with standardized argument $t/\sqrt{\nu}$; and for values of δ determined as $\sqrt{(\nu + 1)}K_p$, where K_p is a standardized random normal deviate with probability integral $1 - p$. The tables were computed on an IBM card programmed computer and are legibly reproduced from photographed typescript. Statisticians will be grateful to the authors and to the Stanford University Press for making this work, which was done under a Naval research contract, available for general use.

Modern Computing Methods

Department of Scientific and Industrial Research: National Physical Laboratory. Notes on Applied Science, No. 16. Pp. vi+129. (London: H.M. Stationery Office, 1957.) 10*s.* 6*d.* net.

THIS work is based on lectures delivered by various members of the staff of the Mathematics Division of the Laboratory during a vacation course on "Computers for Electrical Engineering Problems". It gives a brief account of those computing methods which are likely to be of general use, and its emphasis is essentially practical. There are twelve chapters, the first four of which deal with algebraic problems including the determination of the real and complex roots of polynomial equations, the inversion of matrices and the determination of their latent roots and vectors, and the solution of simultaneous linear algebraic equations. Chapter 5 introduces the theory of finite differences which is used in the following two chapters to solve ordinary differential equations of the boundary-value and initial-value types. Chapter 8 is mainly concerned with quasi-linear partial differential equations of the second order in two independent variables and uses the method of 'characteristics' for the solution of the hyperbolic equations. The treatment of the elliptic and parabolic partial differential equations is given in Chapter 9, and relaxation methods are discussed in Chapter 10. The last two chapters discuss the various problems which arise in the computation, construction, checking and presentation of numerical tables of mathematical functions. The account is necessarily condensed, but it is supplemented by an extensive and most useful bibliography of reasonably accessible literature. S. WEINTROUB

The Physiology and Biochemistry of Lactation

By Dr. S. J. Folley. Pp. viii+153+19 plates. (Edinburgh and London: Oliver and Boyd, Ltd., 1956.) 18*s*. 6*d*. net.

IN the past twenty years the Physiology Department of the National Institute for Research in Dairying, under the leadership of Dr. S. J. Folley, has made outstanding contributions to knowledge of the biochemistry and physiology of lactation. The present book is based on a series of lectures given by Dr. Folley at the Collège de France. It presents a commendably clear and readable account of the important advances that he and others have made in the subject, and adequately describes modern methods by which these advances have been achieved. The first of the six chapters discusses the growth of mammary tissue and how it is influenced by œstrogen, progesterone and some of the anterior pituitary hormones. The second and third chapters deal with the initiation and maintenance of lactation, and the fourth with the milk ejection reflex, the nature of the milk ejection hormone and the effector contractile tissue of the mammary gland. The last two chapters describe modern views on the methods by which milk fat, lactose and milk proteins are formed in the gland. The book is well illustrated, the figures and tables are clear and concise, and a valuable list of references accompanies each chapter. It is a book that can be highly recommended to students, lecturers and research workers and indeed to all whose job it is to understand the functioning of the actively secreting mammary gland. J. A. B. SMITH

The Armored Scale Insects of California

By Howard L. McKenzie. (Bulletin of the California Insect Survey, Vol. 5.) Pp. v+209+3 plates. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1956.) 45*s*. net.

THE wide range of species of the armoured scales, or Diaspididae, to be found in California include many that are primary pests of major agricultural crops. The object of the present work is to enable the thousands of specimens received annually by the State Department of Agriculture to be accurately identified and their occurrence within the State recorded, so that the economic importance of the species may be evaluated. The book, by a well-known authority on this group of insects, is admirably designed to meet this objective.

Keys to genera and species are given as well as excellent detailed figures of each species. The species are not described but the more important taxonomic references are listed and can be consulted where the identity is in doubt. Excellent colour photographs of some of the more important species are included; but it is open to question whether these are of any great aid to recognition, as closely allied forms are often so very much alike in appearance. Type locality and host as well as other known hosts are given for each species as well as other useful information. There are an index to the genera and species, a host index and a host list including the Diaspidid species, arranged alphabetically under plant families.

This book is very well arranged and brings together a wealth of information that will be invaluable to workers in California. But although it deals with the fauna of a restricted area, many of the species have a very much wider distribution, not only in North America but also throughout the world. It will therefore be of considerable value to all those interested in this group of insects of considerable economic importance. W. J. HALL

Rocket Propulsion Elements

An Introduction to the Engineering of Rockets. By George P. Sutton. Second edition. Pp. xii+483. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1956.) 82*s*. net.

IT is surprising that in spite of the growing importance of rockets since the Second World War so few books have been written dealing with rocket propulsion from the point of view of the design and development engineer. When first published in 1949, this book was the only one of its kind and even to-day it has no equal. This second edition brings the subject up to date and remedies some of the weaknesses of the first edition. The book has been enlarged by approximately 60 per cent and includes new material on both liquid- and solid-propellent motors, the subject-matter of the latter in particular being a considerable improvement on the first edition. A more comprehensive treatment of heat transfer is also included, although radiation could have been dealt with more fully. The many worked examples and the problems at the end of each chapter are useful features although the student would appreciate answers to more of the problems. In a book of this nature covering such a wide field it is inevitable that certain aspects of rocket propulsion cannot be dealt with as fully as some people would wish, and so for those wishing to delve more deeply into specialist subjects there is a greatly enlarged and well-arranged bibliography at the end of the book.

This is a comprehensive technical book covering both the theory and practice of rocket engines and can be thoroughly recommended to all those, whether students or practising engineers, who are concerned with rocket propulsion.

Through Alchemy to Chemistry

A Procession of Ideas and Personalities. By Prof. J. Read. Pp. xvii+206. (London: G. Bell and Sons, Ltd., 1957.) 18*s*. 6*d*. net.

THOSE who have an acquaintance with Prof. Read's earlier books, "Prelude to Chemistry" (1936), "The Alchemist in Life, Literature and Art" (1947), and "Humour and Humanism in Chemistry" (1947), will know how ably and with what charm of style he can draw on his fund of specialized knowledge of the chemistry of the past and the personalities of its practitioners. A new book by him in this field may be expected to be good, and this latest one from his pen amply fulfils expectations.

It is, as he says, in some way a digest of the earlier works, to which material from his "Direct Entry to Organic Chemistry" (1949), which was awarded the Cortina-European Prize of a million lire, has been added. The text takes the reader from the ideas of the earliest civilizations through the long period of alchemy to modern times, the age of the benzene ring, electrons, atomic structure, and chemistry in space. The illustrations, including many excellent plates, add interest and understanding to the story; many of them would be difficult to find elsewhere. The book is designed to be intelligible to the educated reader not familiar with the details of chemistry; the only chemical equation in it is $2H_2 + O_2 = 2H_2O$, and anyone who knows the full history of all that lies hidden in this simple expression will have an idea of what could be expounded from such familiar things.

Prof. Read's book can be warmly recommended to all who care for the better things of science; to the chemist, to the young reader who will be attracted by its clarity and interest, to the historian, and to the many who are now aware that the history of science is not only of value in itself but also forms an integral, although sometimes neglected, part of the whole history of civilization.

J. R. PARTINGTON

A Practical Guide to Plant Sociology for Foresters and Agriculturists

By Prof. F. R. Bharucha and Dr. W. C. DeLeeuw. Pp. viii+44. (Bombay; Calcutta; Madras: Orient Longmans Private, Ltd., 1957.) Rs. 5.

WITH the revival of the Botanical Survey of India, the authors have brought out this little book to provide, in easily available form, some tangible suggestions for methods of studying the ecology of Indian vegetation. They have, in fact, outlined the methods of the Zurich–Montpellier school of phytosociology. The difficult task of doing this within the space of forty pages has been well tackled, but it seems questionable whether the emphasis on brevity has not been too great. One cannot help feeling that the inexperienced ecologist, when he comes to use the book for practical field studies, is likely to be left a prey to unsolved doubts as to just how he should begin. Nevertheless, the book does put into his hands useful data on the Zurich–Montpellier techniques, which, with some general guidance, should enable him to contribute towards a systematic description of Indian vegetation.

The book can also serve to give botanists who are unfamiliar with the work of the Zurich–Montpellier school a nodding acquaintance with its methods. That many British ecologists are critical of these methods is irrelevant here, but the widespread lack of understanding between the two schools of thought might be lessened by a better knowledge on both sides.

MAURICE ASHBY

Plastic Design of Portal Frames

By Dr. Jacques Heyman. (Cambridge Engineering Series.) Pp. viii+104. (Cambridge: At the University Press, 1957.) 10*s*. 6*d*. net.

QUITE apart from the interest of its subject, Dr. Heyman's book is attractive because of two features not usually encountered in modern technical publications. First, it is inexpensive, and secondly, it does not pretend to be a fully-exhaustive treatise on a wide field. The text deals with single-story portal-framed buildings only, and does not stray outside the terms of reference so set.

It is worth noting that the conception of the steel frame as part of a finished structure is constantly kept before the reader. He is not given the theoretical background only, and left to apply this to design as well as he can; throughout, the emphasis is on completing the task of translating the ideas developed at Cambridge into the completed building.

Dr. Heyman has the valuable faculty of realizing that the student of his subject may well find difficulties even in the elementary stages. He makes a considerable effort to ensure that the simplest application of plastic design—to continuous beams and purlins—is thoroughly understood, and then builds logically and gradually on this basic understanding until such complex frames as multi-bay portals and tied portals under wind loading are being considered.

The book achieves its purpose of introducing the newcomer to this powerful British method of steel design, but Dr. Heyman realizes the limitations of his space and has confined himself to a type of structure where strength of sections rather than stiffness of stanchions is likely to be the controlling factor. Those readers interested in instability or multi-story construction must turn to the excellent bibliography for further direction.

W. FISHER CASSIE

Trilinear Chart of Nuclides

By William H. Sullivan. Pp. ii+4+chart. (Washington, D.C.: Government Printing Office, 1957.) 2 dollars.

W. H. SULLIVAN'S "Trilinear Chart of Nuclides" has just appeared in its second edition. One can surely say without exaggeration that every nuclear physicist and chemist, and, in addition, the large group of people who require nuclear data in their work, will be delighted to be able to embellish the walls of their offices or laboratories with this very useful atlas of nuclides or, at least, have it handy for ready reference in their desks.

I am sorry to find that the colour scheme of the first edition has been replaced by printing the hexagons in heavier or lighter print for the naturally occurring isotopes and the artificial ones. Even with the advantage of a lower price for the chart, the sacrifice of beauty seems regrettable.

The organization of the new chart is identical with that of the first edition. The amount of information presented is very large, and great pains seem to have been taken to ensure accuracy. At a price of 2 dollars the chart should be extremely popular with the scientific world.

E. BRETSCHER

Complexometric Titrations

By Prof. Gerold Schwarzenbach. Translated and revised in collaboration with the author by Dr. Harry Irving. Pp. xviii+132. (London: Methuen and Co., Ltd.; New York: Interscience Publishers, Inc., 1957.) 21*s*. net.

MOST chemists are familiar with at least a few of these elegant methods, but all will welcome this survey and be surprised at the variety and extent of the applications. More than 300 references are given to papers, nearly all of which have appeared in the past decade or so.

Prof. Schwarzenbach, the pioneer of complexometric titrations, gives a very clear discussion, aided by numerous neat diagrams, of the theory underlying the stability of the complexes and the titrations. The use of dyes as metal-indicators arose from a chance observation made when hard tap-water containing calcium was being employed for washing vessels in which a complexone and murexide had been used. (The chance observation would probably have been wasted had it not been made by the eye of a genius.) The indicators are so sensitive that end-points are very sharp even with 0·01 *M*-titrants.

The use of masking agents, enabling mixtures to be titrated, is fully explained, as is also the preparation of the necessary *p*H buffer solutions. Nearly forty detailed determinations include examples of direct, indirect, substitution, and back titration and suggest many further applications.

This 'translation' is much more than the dry bones often covered by that term, for Dr. Irving has been associated with the author in the preparation of a second German edition and has not hesitated to make such alterations as seemed desirable. There are a few misprints, and some of these are important.

The publishers are to be congratulated on the production of a well-printed and well-bound book at a reasonable price. A. D. Mitchell

Biological Staining Methods

By George T. Gurr. Sixth edition. Pp. vi+102. (London: George T. Gurr, Ltd., 1957.) 5*s*.

THE diversity of staining techniques has increased so greatly in recent years that it is often difficult for the non-specialist to choose those most applicable to his problem. A book of this type, which presents clearly a wide selection of methods, is thus of great value, not only to students but also to all who use staining methods. This new edition of Mr. G. T. Gurr's book follows the plan of previous issues, devoting sections to bacteriological, hæmatological and general methods. Some new techniques have been added, together with a section on fluorescence microscopy, a method which is of increasing importance in biological research. A most useful feature of the book is the expanded formulary, giving the composition of many staining solutions, and also the appendix which lists the solubilities in water and in alcohol of many common chemicals and stains. A possible improvement which might be incorporated in any later edition would be the separation of the histochemical methods from the general stains and their expansion into a separate section. This, however, is a minor criticism, and the book in its present form will, I feel, prove a most useful reference work, particularly to students and laboratory technicians.

S. Bradbury

Metrology and Gauging

By S. A. J. Parsons. Pp. xxii+286. (London: Macdonald and Evans, Ltd., 1957.) 25*s*.

THE ever-present demand for greater precision in manufactured articles has created the need for a wider knowledge of metrological techniques among those engaged in production processes, not least the designer himself. It is becoming increasingly recognized that instruction in this subject should form part of the curriculum of the engineering student, and the book under review has been particularly designed to cover the syllabus requirements of examinations leading to corporate membership of the Institution of Mechanical Engineers and the Institution of Production Engineers, and similar examinations. However, the author's treatment of the subject makes the book equally valuable to the practising engineer.

An introductory chapter deals with the fundamental standards of length, and this is followed by a description of the use of light-waves as length standards and various forms of interferometer embodying this principle.

After a chapter on the interchangeability of components, the author discusses in considerable detail the design, manufacture and testing of limit gauges. This is followed by several chapters on commercially available measuring instruments, which have been grouped according to their principle of operation, namely, optical, mechanical, electrical or pneumatic. The application of these instruments to screw thread measurement and the testing of straightness, flatness and alignment follows. Two chapters are devoted to the measurement of gears and surface finish. The appendixes include a list of relevant British Standards and some typical examination questions.

This book, having regard to its purpose, quite adequately introduces the subject of metrology, and clearly indicates present trends in measuring techniques. However, the author's presentation of his material could have been improved by re-grouping it in a more logical sequence, and the list of chapter contents could with benefit be shortened. The illustrations are plentiful, and a clear fount makes the book pleasant to read. P. W. Harrison

The Rolling of Strip, Sheet and Plate

By Eustace C. Larke. Pp. xi+404. (London: Chapman and Hall, Ltd., 1957.) 63*s*. net.

IN this book a remarkable amount of material has been compressed into one volume. The opening chapter deals with modern rolling plant. Then a chapter on multi-roll mills describes the fascinating Sendzimir mill and its advantages. There follow chapters on roll cambers, gauge variation of rolled strip, rolling loads and rolling schedules. Numerical and graphical methods for computing the latter are fully described in simple terms, and nowhere is the text so condensed that the reading becomes difficult. A whole chapter is given to the influence of coiler and decoiler tension on the rolling load. Then come chapters on deformation, hot rolling and the calculation of hot-rolling loads. Finally, there are chapters on the energy consumed in cold and hot rolling and on the productive capacity of strip mills. This last chapter presents practical methods for calculating the capacity, and effects considered include handling time, waiting time, length and weight of coils and rolling speed.

A considerable part of the book is devoted to methods of calculation, and it may not be out of place to make two comments. The amount of *ad hoc* approximation made in order to simplify complex mathematical equations might be largely avoided by using an electronic computer to solve some of the design problems; and, for complicated situations where the validity of the assumptions leading to the theory are in doubt, there may be something to be gained by using statistical design in experimentation. For example, improvement in the use of existing productive plant may be sought by the use of the Box technique of evolutionary operation.

It is to be hoped that the book will be of interest to mill managers and their technical staff as well as students. L. S. Goddard

Peculiar Disorder of Plasma Thromboplastin Production

One of the several functions of platelets is participation in the formation of plasma thromboplastin. Recently, we encountered in the blood of a patient an agent with the unprecedented action of specifically hindering this activity. Thus, the presence of his plasma or serum in the incubation mixture inhibited the generation of plasma thromboplastin[1]. Compared with a normal control (Table 1) the derangement, as estimated from the clotting time of the substrate, was more apparent on reducing the number of platelets (experiments *B* and *C*) and practically abolished on using a concentrated suspension (experiment *D*).

Table 1. Effect of Platelet Concentration on Inhibitor Activity

Experiment No.	Platelet suspension (10^3/mm.^{3})	Clotting time of substrate (sec.)* Source of plasma or serum Normal	Patient†
A	600	10	14
B	300	12	19
C	150	14	25
D	1,200	8½	9

* Equal volumes of plasma treated with aluminium hydroxide (1 : 5), diluted 1 : 10 serum, platelet suspension and 0·025 *M* calcium chloride were incubated at 37° C. for 6 min. The activity of the mixture was tested by taking 0·1 ml. together with 0·1 ml. 0·025 *M* calcium chloride and adding them simultaneously to 0·1 ml. normal citrated plasma (substrate), and recording the clotting time.

† In this case the incubation mixture contained either patient's plasma and normal serum or patient's serum and normal plasma.

Antihæmophilic globulin and Christmas factor levels[2] were determined in the presence of excess platelets; normal results were obtained. The patient's platelets were fully active in the thromboplastin generation test. Pre-incubation of normal platelets with patient's plasma or serum did not cause further deterioration in the production of plasma thromboplastin, indicating that the inhibitor has a retarding but not a destructive action on the platelet thromboplastin component. Further study has shown that this inhibitor counteracts the combination of platelets with antihæmophilic globulin and Christmas factor; the activity of other blood-clotting factors or their intermediate products were uninfluenced.

Salt Intake, Adrenocortical Function and Hypertension

A recent communication[1] proposed that the high levels of salt consumption current in modern societies were beneficial since the salt stimulated adrenal cortical function and thereby set in motion various adaptive mechanisms that make the individual more responsive to the stresses of modern living. Space does not permit examination of whether modern living actually has more stresses than a primitive life: one American anthropologist, Prof. G. P. Murdock of Yale University, several years ago[2] expressed strong doubts that such was the case.

Although the addition of salt to food is as old as recorded history, many vigorous groups have used none except that which occurred naturally in foodstuffs; for example, Eskimos, certain of the Chinese and North American Indians, the Lapps, and the Masai of Africa. Available data indicate that the sodium intake on these natural diets would range from about 1 to 2 gm. (2·5–5 gm. as sodium chloride) and sometimes less. Beginning with the pioneering work of Allen[3], drastic salt restriction has been used widely in the treatment of various diseases. During the past ten years I have studied some 75 patients in metabolic wards for long periods before and after sodium restriction of 40–175 mgm./day. These people have maintained sodium balance and normal activity, and evidence of impaired adrenocortical function has not been observed. One walking hospital patient has now been restricted to about 115 mgm. sodium/day for more than four years; she remains in electrolyte balance, and numerous clinical and biochemical tests of adrenocortical function, including the response to intravenous adrenocorticotrophic hormone[4], which were made recently, indicated a normally reactive adrenal cortex. In other patients, psychiatric interviews, psychometric studies and electroencephalograms before and after drastic salt limitation revealed no changes. It has been concluded that adrenocortical function is normal on a low salt diet.

Finally, is a high salt (sodium chloride) diet itself disease-producing? I believe there is ample evidence to indicate that salt is a primary cause of 'essential' hypertension which, after atherosclerosis, is the commonest form of cardiovascular disease in Western society. For some years, I have been intrigued by the apparent low incidence of hypertension among many primitive races; it was of interest to find that among such groups for which data were available, a low dietary intake of sodium was a common factor, generally 1–2 gm. per day. (All experimental and clinical evidence indicates that it is the sodium, not the chloride ion, which is toxic.) Up to the present time I have found no reports of groups which habitually consume low sodium diets and have hypertension to any significant degree.

It has been known for several years that feeding salt to rats will produce a disease which mimics human hypertension[5]. Beginning in 1954, I have published evidence indicating that individuals customarily on a high salt diet will have significantly more hypertension than those on a low salt diet[2,6]. It is known that the West Indian Negro has a much greater incidence of hypertension than the Whites in the same area[7], and according to Prof. Murdock the evidence suggests that from early childhood the Negroes eat a diet high in salted pork and fish. The Southern Negroes of the United States have several times as much hypertension as the Southern Whites[8]. My interviews with Negroes from that region indicate that for most of them salted pork in one form or another has been a prominent article in the diet from early childhood.

Prof. A. Halawani, director-general of the Research Institute of Tropical Medicine, Cairo, informed me last year that the Egyptian peasants ordinarily ate large amounts of heavily salted cheese, and when available, salted fish: he had no precise statistics, but it was his impression that hypertension was relatively common among these peasants in contrast to most Africans and Orientals[8].

It has been axiomatic that Orientals have little or no hypertension[8]. From the work of Prof. T. Fukuda, Physiology Department, Chiba University, Japan[9], and a Japanese Government bulletin[10], the following data emerge: (1) hypertension is a widely prevalent and serious disease in Japan; (2) fatal cerebral apoplexy is the commonest cause of death and is 1·5–2·0 times more frequent than in the United States; (3) in the Prefecture of Akita, where hypertensive cardiovascular disease is especially common, the daily sodium chloride intake (based on 24-hr. urinary chloride excretion of 268 adults) averaged 26·3 gm.—about twice the average Japanese intake, and 2·5 times the average intake of the American male[11]; (4) among 2,082 unselected men studied in Akita the following blood-pressure data were found: at ages 20–40, about a quarter had systolic pressures greater than 140 mm. mercury and a fifth had diastolic pressures of 90 mm. mercury or more; at ages 40–60, 35–62 per cent had systolic elevation and 37–50 per cent had diastolic elevation in excess of 140 and 90 mm. mercury, respectively. A similar incidence of elevated blood pressures was found in the 3,219 women who were examined. At corresponding ages this frequency of elevated blood pressures is about twice that of the Japanese population as a whole and is in striking contrast with areas in China and India where low salt diets are the rule and hypertension is a rare or an uncommon disease. I do not know of other areas in which such a high incidence of elevated blood pressure is present, although they presumably exist.

From the foregoing, the following conclusions seem justified: (1) a low salt diet is associated with normal adrenocortical function; (2) a high salt diet is associated with a markedly increased incidence of hypertension and cerebral apoplexy; (3) evidence discussed elsewhere[2,6c] suggests that the high salt intake is a cause of, and not caused by, the hypertension; (4) sharp reduction of current levels of salt intake could be carried out without harm and probably with great benefit, by reducing the incidence of hypertensive cardiovascular disease. Furthermore, I predict that wherever low salt diets prevail (that is, less than about 2 gm. of sodium per day) hypertensive cardiovascular disease will be uncommon; conversely, where high salt diets (that is, more than perhaps 5 gm. of sodium per day) are the rule, hypertension and its complications will be frequent.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

Intestinal Carcinoma in Mice following Injection of Herring-Sperm Deoxyribonucleic Acid

THE transmission of genetical characteristics from one strain of bacteria to another by means of deoxyribonucleic acid is now well recognized. However, apart from the claim by Benoit *et al.*[1] to have altered the hereditable features of certain ducks, the method does not appear to have been applied clearly and successfully to the higher organisms. Nevertheless, it seems theoretically possible, by analogy with the achievements in bacterial transformation, that some characteristics of cancer cells might be transmitted to normal cells by means of tumour deoxyribonucleic acid, and experiments are being carried out here with that end in view.

It was felt that adequate controls should reasonably include not only the parallel administration of normal deoxyribonucleic acid of the same species and strain and preferably of the same tissue as that from which the tumour was derived, but also that of an entirely foreign species which might reveal non-specific effects on cell metabolism. From bacteriological evidence it seemed that direct interaction between the deoxyribonucleic acid of the host and that newly introduced might occur only if the new acid were highly polymerized and derived from a source showing close genetical relationship.

Experiments were carried out on young line-bred *C3H* mice, and the foreign deoxyribonucleic acid chosen was a commercial preparation of herring sperm. In the course of investigations, two three-weeks old females of a litter of four received five daily injections of the deoxyribonucleic acid of herring-sperm. On the twenty-third day after the first injection, one died and the other, being moribund, was killed. Both bore a solid whitish tumour mass involving duodenum, jejunum and mesentery, together with small deposits scattered over the peritoneum and in adjacent lymph nodes. A considerable amount of blood-stained ascitic fluid containing numerous tumour cells was present, and the general picture was similar in both cases.

Histological examination showed an adenocarcinoma arising in the mucosa of the duodenum. In some areas there was tubular differentiation, but elsewhere the tumour was undifferentiated. The solid tumour has been passaged with difficulty to other *C3H* mice but not to other strains. The ascites cells have been transmitted to both *C3H* and albino mice (laboratory strain), resulting in the growth of both solid and ascites forms, with some animals dying as early as six days after injection as a result of tumour proliferation.

The two litter mates (females) which received no treatment have remained healthy, and we have as yet found no reference to such a tumour developing spontaneously in mice of any strain. It is true that we have not so far been able to repeat this result; but in our view the development of a tumour so unusual in its site of origin and in its behaviour in young mice in these circumstances cannot be disregarded. This *C3H* strain of mice has, of course, a high incidence of spontaneous mammary carcinoma transmitted by the Bittner milk factor, which develops normally in adult females. We think it most unlikely that the foreign deoxyribonucleic acid was incorporated into the nuclei of the mouse tumour, but it may well owe its carcinogenic effect to an interference with the synthesis of a normal acid in the cells of the duodenal mucosa, which is developing extremely rapidly at this stage.

If we had achieved this result by using deoxyribonucleic acid derived from a mouse tumour we should have been tempted to suppose that the abnormal acid had been assimilated in the genetical material of the mucosal cells in the manner of bacterial transformations. The production of a tumour in this control group indicates the need for extreme caution in interpreting positive results in work of this kind.

Mast Cells

Influence of Cobalt on White Mouse Skin Mast Cells

Observations on the action of cobalt compounds on living organisms revealed that this is to some extent similar to that of histamine. Therefore, as mast cells may produce and/or store histamine and histamine-like substances attached to heparin molecules, it was of interest to see if the cells examined were influenced by cobalt compounds. These were given intraperitoneally to white mice in a single dose of 100 mgm. cobalt/kgm. body-weight, in the form of cobalt nitrate, acetate and chloride. Another series of mice received 5 mgm. cobalt/kgm. in the same salts daily for 3 weeks. Specimens of the skin were fixed and stained by a modified Nowak and Zahl stain[1].

Within 1–1½ hr. of receiving a single dose of any of the cobalt compounds an enlargement of the granula and an increase of their metachromasy were observed. The nuclei of the cells were enlarged, and amitotic cell divisions that occurred during full secretion activity of the mast cells were seen frequently, after which the cells were destroyed by clasmatosis. The metachromatic granula then lay in the substantia fundamentalis for more than 5 hr. The separate nuclei underwent pycnosis, and after clasmatosis occurred there was no way of measuring them.

In white mice receiving only 5 mgm. cobalt/kgm. the increased activity observed in the above experiments is much less. After receiving cobalt compounds for 23 days the cells described are found fairly frequently in the specimens, almost all being disrupted, with their granulations often orthochromatically stained. They remain in the proximity of the intact cells forming crown-like structures.

When the same concentration of the cationic components of the cobalt compounds were used the results were similar.

From the experiments described above it follows that cobalt may stimulate the activity of the mast cells, cause their disruption and finally their degeneration. It also stimulates mitosis within the range of doses used and in this way may liberate the substances produced by these cells.

Diurnal Variations of the Mast Cell Activity

Work over several years has revealed that mast cells secrete heparin and/or histamine[2,3]. We wished to determine whether there are significant morphological variations of the mast cell activity, similar to those described in other organs examined for 24 hr. The observations were made on white mouse skin at 3 hr. intervals for 27 hr. The specimens were stained by a modified Nowak and Zahl method[1]. The kariometric analysis revealed that a definite rhythm exists in the activity of these cells. Detailed data are given in Table 1. The cytoplasmic granula of the cells are most delicate during the morning, at 6 and 9 a.m. The maturity, that is, the extent of metachromatic staining, is also minimal at these times. The metachromasy of cell granula increases towards the night and reaches a maximum at midnight. Clasmatosis during the day is minimal and increases during the night.

Table 1. Mean Diameters of the Nuclei of Skin Mast Cells during 24 hr.

Hr.	Percentage of nuclei with a diameter (μ)								
	2·4	3·6	4·8	6·0	7·2	8·4	9·6	10·8	12·0
3	0	4	13	47	21	8	5	2	0
6	2	10	37	21	16	9	5	0	0
9	5	11	31	38	10	5	0	0	0
12	1	7	18	43	21	6	4	0	0
15	0	2	9	31	39	14	3	2	0
18	0	1	2	6	22	27	20	17	5
21	0	0	4	15	31	38	10	2	0
24	0	0	6	23	36	19	9	7	0

The results show that mast cells, as probably all cells of living organisms, are influenced by day and night changes. This fact is of interest not only in the examination of the fate of heparin and histamine in the organism, for the diurnal factor must be taken into account as a very significant one in any observations on labrocytes, that is, on mast cells.

A Lipopolysaccharide Antigen of the *Treponema*

Immunochemical studies carried out by D'Alessandro *et al.*[1] on a non-pathogenic, culturable treponeme, the so-called Reiter treponeme, revealed the presence of four antigenic components: (1) a thermolabile protein; (2) a specific, thermostable antigen with polysaccharide characteristics; (3) a lipoid, corresponding to the ubiquitous lipidic antigen cardiolipin; (4) another lipoid similar to the organ-specific cerebral antigen of Witebsky[2]. These studies led to the conclusion that the treponemes, like other organisms, are mosaics of antigens, and a safe basis was established for a better understanding of the complex serological response of the infected host.

In the serodiagnostic field the interest has been focused so far on the Reiter protein antigen, which proved to be a valuable antigen in syphilis serology. The reactivity of the protein antigen, which shows a remarkable specificity and sensitivity, in the complement fixation test with syphilitic serums, is understandable on the assumption that a common antigenic component exists in the Reiter and in the pathogenic *Treponema pallidum*, as indicated by experiments of Dardanoni and Censuales[3].

From the investigations carried out in 1949, the polysaccharide antigen of the Reiter treponeme appeared to be of minor interest from the serodiagnostic point of view. The antigen isolated from the treponemes by trichloracetic extraction of organisms treated with sodium hydroxide, behaved as a haptene: it failed to elicit antibodies in the rabbit and its *in vitro* reactivity with syphilis serums was sparse and weak. These results discouraged further investigations.

However, bacterial polysaccharide or lipopolysaccharide antigens are generally considered to be outstanding components of the organisms in relation to their immunogenicity and *in vitro* reactivity. With this in mind, the problem of the polysaccharide treponemal antigen has been re-investigated in this laboratory. This led to the preparation of a lipopolysaccharide antigen which appears to be clearly reactive in the complement fixation test with syphilitic serums.

Reiter organisms grown in Brewer thioglycholate medium are centrifuged and treated with sodium deoxycholate[4]. Enough 40 per cent trichloracetic acid solution is added to the viscous fluid resulting from the deoxycholate treatment of treponemes to give a final concentration of 5 per cent. The mixture is then kept at 4° C. for 4 hr. After centrifugation the supernate is harvested, the trichloracetic acid removed by dialysis and 4–5 volumes of ethanol added. In a few hours a precipitate is obtained which is centrifuged, redissolved in water and again precipitated. This procedure is repeated three times. The antigen is finally dissolved in water and lyophilized. For use, 1 mgm. of the lyophilized preparation is dissolved in 1 ml. of saline, giving an opalescent solution without sedimentable turbidity.

The antigen inoculated intravenously in rabbits produces antiserums which react definitely with homologous antigen in the complement fixation test; heterologous lipopolysaccharide antigens derived from some Gram-negative enteric organisms did not react with such serums. The Reiter lipopolysaccharide antiserums give a positive complement fixation test with suspension of intact Reiter organisms; similarly, Reiter organism antiserums react with the lipopolysaccharide antigen. Serums obtained from rabbits experimentally infected with Nichols strain of pathogenic *Treponema pallidum* react strongly and regularly with Reiter lipopolysaccharide.

While a small group of normal human serums gave consistently negative results, a positive complement fixation test was obtained in 76 of 85 human syphilitic serums tested so far. Negative results have been observed in nine biologically false positive serums with more or less pronounced cardiolipin reactivity.

Chemical assays of the antigen are now in progress; a phosphorus content of 2·26 per cent has been found, indicating its lipopolysaccharide nature, which appears to be in keeping with *in vivo* and *in vitro* reactivity. From cross-absorption experiments it seems that the antibody reactive with the lipopolysaccharide antigen is not to be identified with either anti-lipid or with anti-protein antibody.

The consistently negative results observed when the lipopolysaccharide antigen is tested with normal rabbit serums or normal human serums and especially biologically false positive serums indicate the specificity of the antigen. The presence of the Reiter anti-lipopolysaccharide antibody in rabbits infected with the pathogenic Nichols strain, and in a high percentage of human syphilitic serums, strongly suggests that an identical or very similar lipopolysaccharide antigen is common to the Reiter and pathogenic *Treponema pallidum*.

Extensive research is needed in order to establish the practical importance of the lipopolysaccharide antigen in the serodiagnostic field. However, in our opinion modern syphilis serology will be based more and more on the detection of the three distinct anti-protein, anti-lipid and anti-lipopolysaccharide antibodies.

Influence of 4-Methyl-2-thiouracil on the Teratogenic Activity of Hypervitaminosis-A

IT has previously been reported that the incidence of deformities of the skull, brain and palate in the young of female rats exposed to the effects of hypervitaminosis-A during pregnancy is greatly increased if large quantities of cortisone are given to the dams during the period of vitamin A administration[1,2]. It has also been shown that this 'potentiating' action of cortisone in relation to hypervitaminosis-A can be abolished by the administration of insulin to the pregnant female[3].

It is apparent, therefore, that the endocrine glands may play an important part in regulating the teratogenic activity of vitamin A. The present communication is concerned with the influence of 4-methyl-2-thiouracil when administered in doses sufficient to cause loss of thyroid activity in the rat.

Female white rats of the Wistar strain, each of which had previously given birth to a normal litter, were used in these experiments. At the beginning of the experiments the rats were given 2,000 I.U. of vitamin D and 50 mgm. of vitamin E by mouth to ensure that they had an adequate supply of these vitamins. Day 1 of pregnancy was taken as the day on which spermatozoa were detected in the vagina at 9 a.m. The pregnant rats were divided into three groups.

Group 1 received 60,000 I.U. of vitamin A acetate daily from the eighth to the thirteenth day, inclusive, of pregnancy.

Group 2 received 60,000 I.U. of vitamin A acetate daily from the eighth to the thirteenth day, inclusive, of pregnancy and, from the first to the tenth days of pregnancy inclusive, was given a 0·1 per cent solution of 4-methyl-2-thiouracil in lieu of drinking water.

Group 3 was given a 0·1 per cent solution of 4-methyl-2-thiouracil in place of drinking water daily from the first to the tenth days of pregnancy inclusive.

Vitamin A was given by intubation. During the course of the experiment each rat in groups 2 and 3 received on average 240 mgm. of 4-methyl-2-thiouracil.

The rats were killed on the twentieth day of pregnancy and the young removed from the uterus and examined for deformities of the skull and brain. The deformity of the brain encountered was exencephaly.

The findings of the experiment are shown in Table 1. It will be noted that the number of young in group 2 is much smaller than that in the other two groups. This is due to the total resorption of the litters in ten animals.

Table 1

Group	No. of rats	Total No. of young	No. of young with deformities of brain and calvaria	Percentage of young with deformities of brain and calvaria
1	12	77	6	7·8
2	18	45	31	68·8
3	9	62	0	0

The most striking feature to emerge from these experiments is the marked effect of 4-methyl-2-thiouracil on the incidence of deformities of the skull and brain. In previous experiments in which cortisone was given in conjunction with vitamin A, the incidence of deformities of the skull and brain was 36·6 per cent. Cortisone was, however, administered on the ninth to twelfth days of pregnancy, that is, towards the end of the critical period for this deformity.

The results of these experiments suggest that 4-methyl-2-thiouracil has a potentiating effect on the teratogenic activity of vitamin A similar to that previously described for cortisone[1,2].

This work was supported by a grant from the Nuffield Foundation which we gratefully acknowledge.

Effect of Trauma on Growth of Hair

It has recently been reported that ionizing radiations produce local stimulation of growth of hair in the rabbit[1]. Subsequent to this observation, the stimulating effect of some nitrogen mustard derivatives was recorded[2], and it was suggested that "It should be of interest to determine whether the observed effects can be obtained with other radiomimetic agents or carcinogenic substances".

It seems to me that no specific effect of radiation or radiomimetic agents is required to explain the observed phenomena. During studies on hair growth I have often observed that simple mechanical trauma such as scratching or cutting the rabbit skin causes a sudden hair growth to occur around the site of injury. The effect is most dramatically seen in the quiescent phase of the hair-growth cycle. A clipped area of skin may stay quiescent and free from hair for as long as 3–4 months at a time. Trauma to the centre of such an area results in growth of hair around the site of trauma, with the result that a tuft of hair is soon seen lying in the centre of the hairless zone. The accompanying photograph (Fig. 1) shows the effect of a small incision, 0·5 cm. long, into the entire thickness of the skin in the quiescent phase of the cycle. Failure to appreciate the mechanics of the hair-growth cycle has led to many errors in the past, and a brief summary of some of the important facts is as follows.

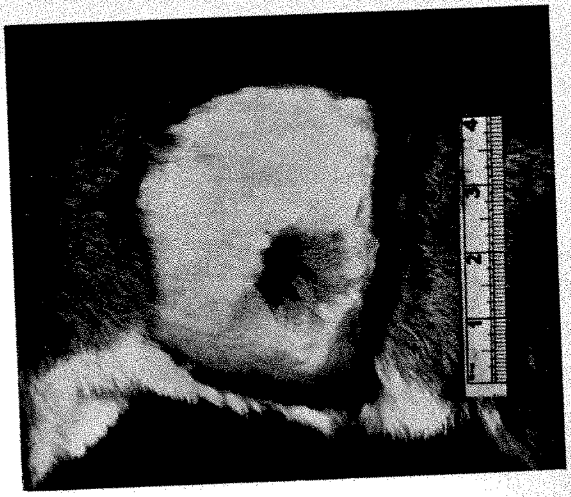

Fig. 1

Hair replacement in the mouse[3,4], rat[5,6] and rabbit[7] is discontinuous and occurs in cyclical waves of active growth. In the mouse and rat cyclical waves of activity start on the ventral surface and spread upwards over the trunk. In the rabbit the hair replacement on the back and flanks occurs in a progressive cycle starting at the dorsum and spreading downwards over the flanks. Hair replacement on the abdomen occurs quite independently of the main dorso-lateral cycle. The progress of a cycle over the trunk creates linear bilaterally symmetrical bands of active growth which can be demonstrated clearly in the clipped animal.

There are many differences between such active and quiescent skin. Hair follicles in the active zone show significantly more mitoses than follicles in the quiescent zones[8]. Proliferative pathological lesions can also be induced more readily in areas where hair growth is active. Thus, painting the rabbit flank with carcinogen produces tumours more quickly and abundantly in an active zone[9]. Inoculation of Shope papilloma virus into skin showing active hair growth and into quiescent skin results in the development of larger and more numerous tumours in the active skin[10]. Intravenous inoculation of vaccina virus into rabbits showed that lesions almost invariably developed in the active zone[10].

In the guinea pig and in man there is no gross hair-growth cycle as seen in the rat, mouse or rabbit. Nevertheless, each hair does show an independent cycle of growth and quiescence. Thus hairs in anagen, catagen, and telogen may be seen lying side by side in any small area of skin in the guinea pig, but they are grouped together in the rabbit and show as large zones of actively growing hair or resting hair.

The problem of growth of hair in man and laboratory animals is of importance not only because of its intrinsic biological significance[6,11], but also because the effect of agents such as X-rays[1] and nitrogen mustards[2] on growth of hair can only be rationally analysed against a background of the dynamic hair-growth cycles and patterns.
